formed on pigs, fowls, pigeons, etc., as well as by experiments on dogs. That a certain number of extirpations of ovarian tumours, in which the abdominal wound is perfectly closed, heal favourably by the first intention without symptoms of peritonitis, is readily understood; but it must not be concluded therefore that the course of all cases of ovariectomy is equally favourable. It can, rather, be shown on physiological grounds, that a certain category of cases must run another course. While cases of the first kind are those in which small tumours have existed a comparatively short time, especially in young individuals whose abdomens have not yet suffered from frequent pregnancies, the latter class is distinguished by the great circumference of the swelling, by its long existence, by the defective condition of the abdominal walls, resulting from age, and perhaps from repeated pregnancies. Hence adhesions occur; and, under these conditions, the abdominal wall becomes distended, and loses more or less of its elasticity. If, now, the tumours be extirpated, the abdominal pressure is rapidly reduced, perhaps rendered *nil*, and hence a total change is induced in the relations of the circulation, exudation, and absorption. These occurrences may be demonstrated in an animal in which air has for some time been blown under high pressure into the abdomen, so as to distend the walls and reduce their elasticity. If the abdomen be punctured, and the air allowed to escape completely, the abdominal wall collapses in loose folds. If the abdomen be opened after six or eight hours, the following appearances are observed in it: free ascitic effusion, hyperæmia of all the viscera, extensive lymphatic stasis of the whole of the small intestine, with tense filling of the large veins and lymphatic trunks. It is plain that in consequence of the sudden renewal of pressure, arterial hyperæmia and exudation have set in, to which the lymphatic and venous stasis, brought about by the defective suction-power of the thorax, may have contributed not a little. The conditions in a patient on whom ovariectomy has been performed are manifestly analogous in one class of cases. As a result of the sudden change in the abdominal tension, an acute transudation must take place. Fluid must also trickle continuously from any adhesions that are present, since the pathological vessels neither close of themselves, nor can they be closed passively, in consequence of the defective abdominal pressure. The paralysed intestine, with its venous stasis, must contribute to the abundance of the transudation, while absorption is interfered with just as in the experiment. The weakening of respiration constantly observed after chloroform-narcosis, the generally depressing influence of the operation on a sick person, may also have an influence. Hence, in a certain number of hours after ovariectomy, there must be a sero-sanguinolent effusion in the abdominal cavity, and, if air be admitted, this must undergo decomposition. In proportion as the local and general conditions again approach the normal, absorption takes place, and more or less distinct septicæmia must be the necessary result. As regards the further course of the case, three things may occur. 1. The quantity of effused and decomposed fluid remains moderate, so that the resisting power of the patient overcomes the degree of septicæmia. 2. The quantity is so considerable that, especially if it pass rapidly into the circulation, death is produced by acute septicæmia with well marked toxic sym-

ptoms. In such a case, care must be taken not to omit an examination of the heart and kidneys for pathological changes, or of the blood for the presence of septic organisms. 3. If absorption of the decomposed materials take place slowly, the patient presents the symptoms of chronic septicæmia; at the same time, if the irritant putrid fluids stagnate in the peritoneum, exudative peritonitis sets in, the products of which in their turn decompose and add to the disastrous effects of the first effusion. Sooner or later, under these circumstances, the result is fatal unless the patient's constitution be of extraordinary strength. In all these cases the septicæmia is the dominant factor, and the peritonitis is of secondary importance. The therapeutic indications in the different cases are hence quite different. In a certain number of so-called 'favourable cases' the abdominal wound may be perfectly closed at once, in the hope that it will heal along its whole extent by the first intention. In the second category of cases, the indications are either to precede the exudation, to prevent its decomposition, or to guide the decomposed matters outwards as soon and as completely as possible. 1. Transudation may be hindered by the restoration of abdominal pressure by means of the application of bandages after the operation; or perhaps semilunar pieces may be cut out of the abdominal wall and the edges brought together with sutures. 2. Decomposition may be prevented (a) by Lister's spray. On theoretical grounds, it is *a priori* very improbable that the agents of putrefaction in the air which almost resist a boiling heat will be destroyed by a two or two-and-a-half per cent. solution of carbolic acid. Wegner has observed in a number of cases that after the use of Lister's spray there are always organisms in the exudation, though in smaller quantity than in other circumstances. (b) Decomposition would be prevented much more completely if, in cases of ovariectomy, the air that has access to the wound could be filtered through cotton-wool. In the after treatment, the safest plan appears to be to remove the secretions early and completely, by means of Marion Sims's plan of drainage through the lowest part of Douglas's pouch.

Herr Olshausen, of Halle, fully recognised the importance of Herr Wegner's observations. Some of them were already confirmed by observation, such as the collapse as the result of reduced temperature, generally attributed to shock. The frequency of this was generally in direct relation to the duration of the operation; and thus were explained the directions of the English operators with respect to raising the temperature of the room, clothing the body with wool, etc. Wegner's view that the performance of the operation under spray increased the number of deaths by shock, appeared to be confirmed by experience. Nussbaum had lost five cases out of twenty-one; none by septicæmia, but most of them by shock. Drainage through Douglas's pouch gave good results. The question now was, whether preference was to be given to it or to strict antiseptic precautions. On this, experience must decide. Marion Sims himself had given up the plan of drainage which he had devised; and Spencer Wells was opposed both to the antiseptic method and to drainage in ovariectomy. The object of drainage was the removal from the abdominal cavity of matters capable of decomposition, not of peritonic exudation. Peritonitis did not kill of itself, but through the absorption of septic matter.—Herr Tillmanns called attention to the danger of abdominal

plethora, and referred to Ludwig's experiments, which showed that ligatures of the portal vein caused death within an hour.—Herr Ziemssen, of Aix-la-Chapelle, observed that Dr. Thomas Keith had had excellent results. He operated very slowly, and did not close the wound until all bleeding had been arrested.

Granular Growths and Tumours of the Larynx.—Herr Wilhelm Koch, of Berlin, related a case which had occurred in his practice. On November 5, 1875, in company with Dr. Schmiedeberg, he performed tracheotomy on a boy aged three-and-a-half, suffering from severe dyspnoea, the consequence of diphtheria. In the course of three days, diphtheritis of the wound appeared, and proceeded so rapidly, that within forty-eight hours there was a dirty ichorous sore, reaching from the thyroid cartilage to the incisura jugularis of the sternum; at its base the trachea could be seen, while the lateral parts of the neck were red and much swollen. The energetic application of the actual cautery arrested the destructive process so rapidly that the necrosed parts were thrown off some days later, and the parts began to be covered with healthy granulations. Contrary to expectation, there was scarcely any loss of substance from the opening in the trachea. The cannula was removed without difficulty on the ninth day; and the case went on well, although there was complete paralysis of the muscles of the œsophagus and larynx, on account of which it was necessary to use the œsophageal sound for a fortnight. In the beginning of December the wound had cicatrised, the paralysis, as well as albuminuria, had disappeared, and there was only slight pains of the lower limbs. One day, while faradisation was being applied, the child became dark red in the face, and made some whistling inspirations. This paroxysm soon passed away, but again occurred on the next day. On December 14, Dr. Koch found the child with strongly marked difficulty of breathing, the only cause of which that could be assumed was an obstruction in the air-tube, probably at the site of the incision, the result of granular growth in the cicatrix. Tracheotomy was easily performed without anaesthesia. There were found four or five pale flaccid pedunculated granulations, each as large as a pea, which had evidently been developed when cicatrization began; taken together, they were about as large as a raspberry. After they had been removed by a Daviel's scoop, respiration went on normally even when the opening was closed with the finger. The wound was therefore allowed to heal at once, without using a cannula. The child appeared to be cured; but as early as January 2, the attacks returned, whenever he cried, the breathing became difficult and prolonged, and at the middle of the month there was constant dyspnoea. On February 10, tracheotomy was performed for the third time. The operation was very difficult; the trachea was, however, opened, and a cannula introduced. Next day Dr. Koch proceeded to examine the air-tube with a sound, when a violent attack of cough brought into sight a dark red bladder about as large as a cherry, which burst on being seized with forceps. It was found to have a dark red peduncle attached to the mucous lining of the cricoid cartilage, and the same peduncle also supported several granulations, three of which, as large as cherry-stones, were removed. It was found that the child could breathe even when the cannula was removed, the remaining peduncle being probably so much contracted as not to be capable of producing obstruction.

In commenting on this case, Dr. Koch remarked that the granulations in the immediate neighbourhood of a tracheal wound appeared to grow exuberantly, and to penetrate into the air-tube. The inspiratory effort must act energetically on the vessels of the granulations, and lead to their distension with blood and oedematous effusion, as was shown by the bladder filled with serum found during the second operation. Granular growths might also occur at other parts besides the opening in the trachea or larynx, in cases of diphtheria. Dr. Koch had seen a polypus with a long peduncle at the level of the cricoid cartilage, where it could not have been due either to the operation or to the cannula. A third cause of granulation-growth was the ulceration of the trachea produced by the pressure of the cannula. Anatomically different from these formations were the cases in which the diphtheritic ulcerative process undermined the trachea, leading to the formation of tongue-shaped lobes, which obstructed the calibre of the larynx, and were capable of increase in size. The transition to cicatricial narrowing was attended by the swelling arising from phlegmonous infiltration of the mucous membrane of the trachea, which, especially in young children, might end in true stricture. In regard to diagnosis, it must be remembered that there might be a combination of the morbid changes above described. As regarded treatment, Dr. Koch recommended that the cannula should be left in for several weeks after tracheotomy for diphtheria, and that the wound should be cauterised several times.

Electric Apparatus.—Herr Mosengeil, of Bonn, showed his electrodes for the purpose of closing, opening, and changing the current during application.

Treatment of Ventral Hernia.—Herr Hadlich, of Heidelberg, described an operation devised by Herr Simon for the operative treatment of ventral hernia at the linea alba. The operation appeared to have been perfectly successful, especially in preventing a recurrence of the affection in subsequent pregnancy.

Frost-Bite of the Nose.—Herr Riedlinger, of Würzburg, related a case of redness of the nose following frost-bite treated by the subcutaneous injection of ergotin (one part in six) over the nasal bone. Symptoms of cerebral anaemia appeared after the injection, but soon disappeared. The condition of the nose was improved.

Demonstrations of various interesting cases were given on two of the days in the operative theatre of the hospital.

The session was closed with some remarks by the President.

ACADEMY OF MEDICINE IN PARIS.

April 25. *Gastrotomy.*—M. Léon Labbé read a note relating to a case of gastrotomy performed in order to extract a foreign body (a fork) from the stomach. It related to the famous fork swallowed by a young shopman. From March 4, 1874, the date of the accident, the patient went through different changes; during some months he resumed his occupations, but his sufferings became so acute, especially after meals, that it became necessary to contemplate extraction. On April 9 the patient was chloroformed, and the operation commenced. M. Labbé had decided on the caustic plan, but, adhesions not coming on according to his wishes, he

made an incision into the abdomen, then into the wall of the stomach, after having previously raised and freed the edges. The index finger of the left hand, introduced into the open wound, allowed him to feel the fork. With the aid of a sound he turned it gently round, and finally drew it out. The abdomen was then covered with a thick layer of collodion to contract the tissues, and iced champagne was administered to the patient. The envelope of collodion hastened the restoration of the tissues to their place. The respiratory rhythm had become greatly modified under the influence of this compression. The fistula became smaller, and it was hoped that it would disappear in a few weeks. The patient was as well as possible, and perfectly able to take solid food.

Etiology of Stone.—M. Debout d'Estrées read a memoir on the causes of stone, studied at Contrexéville. Calculi or gravel might (1) pass from the kidney into the bladder, inducing nephritic colics; (2) remain in the kidney and become developed there; (3) remain in the ureter and bring on serious complications; (4) become the nucleus of larger or smaller calculi in the bladder; finally, in exceptional cases, break up in the bladder and come out spontaneously.

Lead-Colic and Colic of Tropical Countries.—M. Le Roy de Méricourt resumed the question of dry colic in hot countries. The list of symptoms is identical with that of lead-colic. The cases of so-called dry colic have multiplied in a remarkable manner since the extension of steam navigation with engines loaded with lead. In his opinion 'there is no such thing as endemic colic of tropical countries.'—M. Briquet would like to see the term 'lead-colic' replaced by that of 'abdominal myosalgia,' since the pain has its seat in the preabdominal muscles, and not in the intestine.—M. Ruzé de Lavison was of opinion that M. Le Roy de Méricourt was too exclusive. There is a true dry colic, observed not on board steam-vessels, but on the coast and in the interior of tropical countries, which cannot be erased from the nosological list.

May 16. *Dyspepsia.*—M. Leven read a memoir on dyspepsia. He enumerated the numerous varieties allowed by Sauvages, Cullen, Pinel, etc. Then came Broussais, who upset everything, and put gastritis in the place, not only of dyspepsia, but of the majority of diseases. Barras was one of the first who protested against this, and invented gastralgia, as one of those forms of dyspepsia in which the element of pain predominates. What is common dyspepsia? Is it independent of phlegmasia of the stomach, and is it but a functional lesion? M. Leven sought the solution of these questions from experimental pathology. For the dog, as well as for man, there are foods easy and difficult of digestion. In the case of the dog, meat is digestible, fat is indigestible; a meal of fat alone makes the animal dull and uneasy. If the stomach be examined two hours after such a meal, traces of a more or less acute phlegmasia are found, the vessels, nerves, glands, muscular coat, all the elements of the organ are changed. This transitory lesion will continue to increase if the defective alimentation be persevered with. In the human subject, the assemblage of symptoms called dyspepsia have the greatest analogy with those shown by the dog. If the analogy of structure existing between the stomach of a man and that of a dog be taken into consideration, it may fairly be deduced that indigestible food has the same irritant effect in man, and that the anatomical lesion

is the same, transient in the first instance, and disappearing if the alimentary regimen be good, and on the contrary, developing itself, if the alimentary conditions be unchanged. We cannot, therefore, with Beau, consider dyspepsia as a simple functional lesion, nor with Barras, as a gastralgia or a simple neurosis. M. Leven considered that simple ulcer of the stomach is always connected with a previous dyspeptic condition; he does not admit Virchow's theory of its formation by thrombosis or embolism. He had tried, in conjunction with M. Bochefontaine, to produce these ulcerations experimentally by injecting lycopodium powder into the arteries of the stomach, but had never succeeded in doing so. The numerous arterial anastomoses of the gastric tissue suffice to compensate for the effect of the plugging of one of the vessels. When thromboses are present, they appear to be always due to the ulceration itself. In fine, all the symptoms of dyspepsia should be referred to inflammation of the mucous membrane and the subjacent tunic. The acceptance of these dyspepsias as pure functional lesions must be given up.

May 23. *Lead-Colic.*—M. Mialhe, resuming the question of lead-colic, showed that very small doses of lead, if long continued, were enough to bring on colic.—M. Duchenne, of Boulogne, recorded a case of lead-poisoning in a woman whose daily occupation was to wrap up tea in tin-foil, and in whom, consequently, the metal only came into contact with the palm of the hand, and the fleshy extremity of the fingers.—M. Ruzé de Lavison did not share this opinion; he did not believe that a small amount of lead is sufficient to produce the disease. He did not think that the use of lead-reservoirs and lead-pipes sufficiently explain lead poisoning.—M. Mialhe was of opinion that the comparatively frequent occurrence of lead-poisoning on board-ship bears relation to the constant presence of basic alkaline chlorides in the sea-air. Hence arises the necessity of restricting the use of lead and lead compounds as much as possible at sea.—M. Le Roy de Méricourt, in reference to the term saturnine myosalgia, proposed by M. Briquet, believed that this term represents but incompletely the assemblage of symptoms brought on by lead-poisoning. Faradisation is not so efficacious as M. Briquet asserts. It is not by this means that the differential diagnosis between lead-colic and the dry colic of hot countries can be established. According to this speaker, the doctrine of telluric miasmata, so far as it concerns the dry colic of hot countries, leads to nothing, whilst that of lead-poisoning is fruitful in successful results, since from it arise a certain prophylaxis and efficacious treatment.

ACADEMY OF SCIENCES IN PARIS.

March 20. *The Water of the Seine.*—M. Boussingault communicated the result of the analysis of the water of the Seine taken on March 18, 1876, above the bridge of Austerlitz. The results were—ammonia, 33 centigrammes; nitric acid, 1 gr. per cubic meter.

Muscarine.—M. Alizon sent a paper on *Amanita muscaria* or *Agaricus pseudo-aurantiacus*. Besides the usual phenomena of poisoning, experiments have shown, in birds especially, clear symptoms of asphyxia and great disturbances of calorification. After the subcutaneous injection of a sufficient dose of muscarine into a frog, the heart stops in diastole, whilst retaining its muscular irritability. Atropine prevents.

the production of this effect. A small fragment of muscarine placed on the heart also induces diastolic stoppage, even after preliminary destruction of the entire cerebro-spinal system. Atropine appears to act differently from a large number of other alkaloids which re-establish the cardiac contractions after the action of muscarine. In mammalia, muscarine first produces acceleration of the heart-beats, then slackening; arterial pressure gradually falls and rises under the influence of atropine. In the respiratory organs are observed, 1st, an increase in the number of the respiratory movements, then a gradual return to the normal amount (small doses); 2nd, an increase followed by a decrease (medium doses); 3rd, a progressive diminution until the final stoppage (poisonous doses). All these modifications are observed after the preliminary section of the pneumogastric nerves, and disappear by the use of atropine. The disturbances of temperature are as follows: 1st, a slight rise in the temperature, not constant, and appearing one or two hours after poisoning (small doses); 2nd, a fall from 1 to 2 degrees, then a return towards a normal temperature (medium doses); 3rd, a very decided fall preceding death (poisonous doses); 4th, the raising of the temperature by atropine.

April 10. *Sugar in the Blood*.—M. Claude Bernard continued his historical and critical account of the formation of sugar in the blood (see meeting of January 17). These experiments tended to show that the only exact process for finding sugar in the blood, is that which has been followed by Magendie, and by Tiedemann and Gmelin.

The Size of Organs.—A paper by M. Franck related to the change in the size of organs in their relations with the circulation of the blood. By the aid of a special apparatus, the writer recorded the following facts. The hand undergoes variations in bulk, of which the progress is identical with that of the pulsations of the radial artery. The size of the hand decreases during respiration, and increases during expiration. Arterial compression diminishes the size of the organ, and venous compression increases it. Coldness or faradisation of one hand diminishes the size of the other by reflex action.

The Spleen.—MM. Malassez and Picard communicated the results of their new researches on the functions of the spleen. Washings out of the spleen had demonstrated to them that iron exists in that organ in the condition of hæmaglobin, independent of the blood contained in the vessels.

The Acoustic Nerve.—A paper by M. Cyon was designed to show the physiological relations existing between the acoustic nerve and the motor apparatus of the eye. The conclusions of this memoir may be summed up as follows. 1. Disturbances in the motor apparatus, occasioned by operations on the semicircular canals, are not produced in an uniform manner in animals of different species; in frogs, these disturbances are limited almost exclusively to the vessels of the trunk; in pigeons, the muscles of the head are principally affected; in rabbits the disturbances are specially those of the muscles of the eye. 2. The opinion lately maintained by M. Goltz and M. Cyon, and accepted by the majority of physiologists, that the loss of equilibrium which supervenes on the section of the semicircular canals is caused by the erroneous ideas conceived by the animal operated on regarding the position of its head in space, can no longer be maintained. 3. The movements of the eyeball are not compensatory

movements; they are the direct and immediate consequence of the lesion of the canals. 4. By the excitation of the horizontal canal in the rabbit, a rotation of the eye on the same side is produced, so that the pupil becomes directed backward and downward; that of the posterior vertical canal produces a deviation of the eye, with the pupil directed forward and a little upward; that of the anterior vertical canal backward and downward. 5. The excitation of a canal always produces ocular movements in both eyes; but, in the eye of the side opposite to the injured canal, movements in a contrary direction to those of the eye of the other side take place. 6. The pupil contracts on the side on which the excitation takes place, and remains dilated on the opposite side. At the very moment of the excitation, the contraction of the motor muscles of the eyeball has a tetanic character. 7. The oscillatory movements disappear when the acoustic nerve of the opposite side is divided. Fresh excitations of a semicircular canal no longer produce anything except tetanic excitations. The excitation of an acoustic nerve, produces violent rotations of the two eyeballs. 8. The division of an acoustic nerve induces a strong deviation of the eyeball of the same side, so that the pupil becomes directed downwards, whilst on the other side the eye is carried upwards. This deviation disappears after the section of the second acoustic nerve. 9. The movements of the head and trunk observed in pigeons after the lesion of the semicircular canals, are described in a very precise manner by Flourens in his classic writings.

Persistence of the Intermaxillary Bone in the Human Subject.—M. Rougon recorded traces of the separation of the intermaxillary from the maxillary bones in modern human crania, found in the mountainous region which stretches from the Dômes to the Dores, in the department of the Puy-de-Dôme. He had never observed this characteristic in any cranium from the Limagne, even in the lowest types, any more than in the neighbourhood of Paris; the only French cranium of which he was aware as presenting this peculiarity, was that of a prognathous young woman, found in the environs of Saint Acheul. It is a question whether this fact should be regarded as a characteristic of one of our most ancient races, or simply as a local peculiarity resulting from degrading influences.

April 17. *Amygdalitis*.—M. Bouchut presented a note on chronic caseous amygdalitis. He observed that there are chronic anginae characterised by the permanence on the tonsils of white points and spots, which cause much anxiety in families, but, however, are of no importance. These white spots are caseous products which have their origin in follicles of the hypertrophied tonsil, attacked by chronic inflammation. They are formed of fatty matter, odorous or inodorous, and vary from the size of a grain of hemp-seed to that of a mulberry, which they sometimes resemble in external roughness. They remain unchanged for weeks and months, and are reproduced as fast as they are removed with a curette, with which, if this plan be persisted in, they may be permanently removed.

Electrical Variations of the Muscles.—At the meeting of April 24, M. Marey communicated a note on the electric variations of the muscles, more especially of the heart, studied by means of Lippmann's electrometer. The general result obtained by these experiments showed that the phases of the

electric variation of a muscle are similar to those of the work done by it.

Arsenic.—M. Braine communicated some indications as to the chemico-legal search for arsenic. The conclusions of this memoir were as follows. 1. The chemical expert ought to use in the chemico-legal search for arsenic or antimony a very large flask, a third or fourth part filled, and to introduce into it alternately in small quantities acidulated water and the suspected liquid; in this way the arsenic or antimony, however small may be the quantity in the liquid tested, will always be either entirely or in greater part collected in the condensing tube. 2. The method of reagents by the gaseous method is very superior to any other method in the search for arsenic and antimony. Five or six reactions, and even more, may also be produced at will on a very small quantity of material without displacing it. The deposit may also be volatilised, oxydised and caused to crystallise, entirely or in part in the condensing tube, closed at both ends, and afterwards opened to submit it like arsenic and antimony themselves in a liquid condition to the action of appropriate reagents of the gaseous method. 3. This method may be employed with equal advantage to characterise the arsenic and the antimony which will be mixed together, after having separated them by a proper degree of heat, either in the metallic state, or after a preliminary oxydation. 4. As arsenic frequently brings with it bodies in the utricular condition into the condensing tube of Marsh's apparatus; and as arsenious acid may there show dimorphism or other anomalies of crystallisation, experts ought to take notice of these peculiarities. Arsenic and antimony are best tested for by the method depending on the formation of gaseous compounds of those metals.

Pulmonary Respiration.—M. A. Sanson presented a paper on the study of pulmonary respiration in the larger domestic mammalia. The species and race influence pulmonary respiration; the more uncovered surface is displayed by the lung, the more carbonic acid is eliminated by the animal; the male shows a greater activity of respiration than the female. The gaseous mixture contained in the lungs is more frequently renewed in the young than in the old. Alimentation, provided it does not modify the general condition, does not exercise any influence on the pulmonary respiration; neither does labour, when it is over. Temperature has a very decided influence on the elimination of carbonic acid, which increases with heat; atmospheric pressure acts in an inverse manner. Thus the elevation of the temperature may compensate for the lowering of the pressure.

BIOLOGICAL CONFERENCE AT SOUTH KENSINGTON.

The first Conference of the Biological Section was held May 26, at the Loan Collection of Scientific Apparatus, at the South Kensington Exhibition. Dr. J. Burdon Sanderson, the President of the section, opened the proceedings with an address. He said those subjects of which the collection contributed the best examples might be classed as follows: first, the methods of registering and measuring phenomena exhibited by plants and animals; secondly, the methods of investigating the eye as a physical instrument; and thirdly, the methods of repairing the tissues of plants and animals for

microscopic examination. He proposed to confine his remarks to the first of these. He considered that the study of the life of plants or animals is, in a very large degree, a matter of measurement, as we must compare the object studied with some well-known standard, which is really but a method of measurement; and he wished to impress that, in biology, comparison with standards is quite as essential as it is in physics and in chemistry; biology, however, differing from these sciences in not being immediately concerned in establishing standards, but accepting those which these sciences supply. Even microscopes, which are the first objects which strike one on visiting this collection, may be regarded as measuring instruments. Not wishing to dwell upon the application of measurement to the form of the blood corpuscles, he turned to the question of the number of the corpuscles, which is of value to the pathologist and physiologist as a means of ascertaining the quantity of that very important substance, the colouring matter of the blood. This may be determined with tolerable accuracy by chemical means, by estimating the amount of iron in a given quantity of blood; but the process is a slow one, and the quantity required is considerable. The microscope supplies a method by means of which we can find out this important fact from a single drop, such as we can obtain from anyone's finger. He reminded his audience that a cubic millimètre, *i.e.* the cube of 0.04 inch, contained five millions of these blood corpuscles. This number would be, of course, too many to count; therefore a smaller quantity of the blood must be taken. The way in which this is accomplished is the following. A capillary pipette, which will only take up one cubic millimètre of blood, is filled; this blood is then diluted with two hundred and fifty times its bulk of serum; of this diluted fluid a layer, one-fifth of a millimètre, is examined under the microscope, by means of an object-glass, which is covered with a perforated plate one-fifth of a millimètre in thickness; of this the square of the fifth of a millimètre may be cut off by a micrometer, and the number of corpuscles readily counted. He next called attention to the mode of measuring the time occupied by a reflex process, such as sneezing, etc., which processes are found to consist of three stages: first, the stage of reception of an impression; secondly, a stage corresponding to the changes in the brain; and thirdly, the process by which the effect is conveyed to the muscles which act. This measurement is usually represented graphically by marking the periods upon a revolving cylinder. The periods are marked by signals given through the means of a voltaic circuit, and an apparatus by means of which a variation in the circuit can be made so as to record a signal. The same act may record the time of a signal on the cylinder, and send an impression to a sensory nerve; the individual experimented upon may then make a signal as quickly as possible, and thus the time required for the three stages is recorded on the cylinder. The time occupied by these different stages may be analysed by varying the conditions of the individual—*e.g.*, 1. when he knows the time when the signal is to be given; 2. when he expects the signal but does not know the time; 3. when he does not expect the signal. The experiments were then performed, and the tracings handed round. In each of these experiments the time differed, being longest in the last and shortest in the first. The

exact measure of the time occupied by each of these periods may be then compared with a physical standard. For this purpose, a tuning-fork of a known rate of vibration is made, by means of a little brass pointer, to scratch a record, say of each hundredth part of a second, on the paper side by side with the records of the various signals. Thus, a comparison with an absolute standard of time is effected.

Dr. J. D. Hooker then demonstrated the plans, and described the arrangements contemplated in the laboratory which is in process of erection at the Royal Gardens, Kew, for the purpose of the investigation and study of physiological botany. He believed that the establishment of this institution would promptly lead to good work and to the advancement of scientific botany in England, which country, he considered, had already done more for botanical science than any other.—Professor W. T. Thiselton Dyer then demonstrated an apparatus constructed by Professor Reineke for observing the velocity of the growth of plants. This instrument keeps a record of the progress of growth by making and breaking a voltaic circuit at certain stages of progress. By means of the instrument, it has been found that the maximum rate of growth takes place at dawn and the minimum about evening twilight; the rapidity of growth diminishing during the day and increasing during the night. He also demonstrated an apparatus for showing Knight's experiment on the influence of gravity on the direction of the growth and stems of budding plants. The seeds are fixed on needles, which radiate from a disc of cord set on an axis, which can be turned at once.—Professor Marey then proceeded to explain some of the instruments in his collection. He considered that it would be desirable that a physician should be able to see through his patient as if he were transparent. This not being possible, we must attempt by every mechanical means at our command, to explore the various organs and parts, and to study their functions. He hoped to be able to demonstrate the mode of application of some means of investigation which had been recently introduced by him. To study the motions which occur in the internal organs of the body, the most accurate method is that of graphically representing the amount of motion and the time it occupies. We cannot, however, apply the organs directly to the recording cylinder; he, therefore, had contrived a means of transmission of the motions by which they may be communicated to an air-containing cavity, which is covered on one side by thin elastic membrane; from this the movements are transmitted through a hollow tube to another similar cavity (tambour), the membrane of which moves a lever, which may be made to record its movement on a cylinder worked by watch-work. He then proceeded to demonstrate the application of this method to the movements which occurred in muscles when thickening, which occurs while their length contracts. He also showed his well-known stethograph in action, and applied the same method to record the movement produced on the chest-wall by the heart-beat—cardiograph. He then demonstrated the ordinary sphygmograph, and also how the pulse-tracing might be recorded by means of the same method of transmission of one tambour to another. Finally, he gave an account of a new and beautiful method of recording the amount of blood contained in the vessels of the hand under different circumstances. This consists of a glass vessel full of water, into which the hand can be thrust and

fastened in, so as to be immovable and air-tight; from the upper part of the vessel a tube passes, which, when connected with a tambour, registers the changes in the bulk of the hand. These changes in bulk must of course be caused by the varying amount of blood contained in the part, as the hand can increase in size in no other way. Thereupon the lever connected with the tambour moves with each beat of the pulse, and by means of this instrument it can be shown that when the muscles of the hand are in action a greater supply of blood goes to them.—Mr. Schäfer demonstrated Ludwig's apparatus for showing the action of various poisons on the heart of a frog cut out and attached by the aorta to a small recording mercurial manometer. The poisons are supplied from a small funnel a few inches above where they are mixed with the serum feeding the heart.—Mr. Gilbert then made a communication on the subject of the mode of formation of fat in animals. His results, which were obtained some years ago by fattening pigs on various dietaries, did not appear to correspond exactly with those of Pettenkofer and Voit.—Mr. Sclater called attention to the great utility of Zoological Gardens as a living natural history museum. He then referred to some beautiful drawings which were contributed by the Zoological Society to the collection, and which ornamented the walls of the biological section.—Mr. Gaskell explained a diagram of an apparatus called the plethysmograph, conceived by Dr. Mosso, for registering the amount of blood in the forearm. He also demonstrated a model of the recording apparatus. The whole thing consists in a water-tight case, into which the forearm can be introduced, and which, when filled with water, communicates with a glass vessel balanced on pulleys, in such a way that the least overflow from the water-case causes an alteration in the level of the latter, the small balancing weight being so adjusted as to record on a slowly rotating cylinder. This instrument is extremely sensitive, so much so that the least change of mental condition producing an increase in the blood-supply of the brain caused a corresponding decrease in the amount of blood in the arm.—Dr. Lauder Brunton demonstrated many forms of instruments for calculating the elasticity and contracting energy of muscle—myographs, etc. By means of these instruments, he showed how it was proved that the elasticity and contractility of muscle act in accordance with certain laws which make them most advantageously circumstanced for performing rapid and powerful movement.

On Monday, May 29, Dr. Klein described some instruments sent from Prague by Professor Hering, one of which was devoted to artificial respiration, and the others to recording the tracings of various vital phenomena.—Professor Rutherford demonstrated the mode of using the freezing microtome devised by him, in which the preparation to be cut is frozen in gum-solution, and, while still under the influence of the freezing mixture, can be cut in an ordinary microtome.—Dr. Urban Pritchard described several other forms of freezing microtomes; and demonstrated one which he himself had contrived, which for simplicity and rapidity of action seemed to stand alone.—Professor Gerald Yeo demonstrated some microtomes used when the preparation is imbedded and not frozen: the most striking of these are Fritsche's inclined plane microtome, and the quadrant microtome for varying the angle of section.—Professor Flower showed a new method of ar-

ticulating museum skeletons, so that each individual bone could be examined by the student.—Professor Donders demonstrated the use of many of the instruments in his special collection. The cyclo-scope consists of a head-support and a movable arc, in various parts of which induction-sparks can be produced. These in a dark room look like stars, and then the field of vision may be investigated. By means of the isoscope, the angle of meridians of apparent vertical and apparent horizontal direction, either separately or together, at any degree of inclination of the plane of fixation, and at any degree of convergence of the lines of fixation is determined. He also showed the horoptroscope, for the determination of the horopter plane at various degrees of inclination of the plane of fixation, and at different degrees of convergence. He also demonstrated the mode of using the noematachrometer and the noematograph.—Dr. Royston Pigott gave an accurate description of a new refractometer, for ascertaining the mean refractive index of plates of glass or lenses.

CORRESPONDENCE.

THE CONSTRUCTION OF OPHTHALMOSCOPES.

(To the Editor of the LONDON MEDICAL RECORD.)

SIR,—Would you kindly allow me a few words in regard to the construction of ophthalmoscopes? I regret to see from a review of my *brochure* on refraction as determined by the ophthalmoscope, which appeared in your issue of April 15, that I may have unwittingly done injustice to English inventors. This is all the more annoying to me, as I have always recognised the fact that England's contributions to physiological optics, though freely drawn upon by others, have never been as adequately acknowledged as they deserved. To find myself, therefore, even by implication in this category, distresses me.

In the review in question, it is stated, *à propos* of various ophthalmoscopes now in vogue, that the author 'describes modifications which he seems not to know were proposed in England as far back as the beginning of 1873.'

The point of this, I take it, is not that I describe these modifications, but that I fail to give credit to those who originated them, and that I assume for myself what is really due to others. If this be true, no one could regret it more than I; and the writer of the review, Dr. Purves, is right in supposing that I was ignorant of the fact, and still am.

Of the modifications of the instrument which are described in my pamphlet and which bear the slightest resemblance to those of English make, the first devised by me appeared in 1869, and the others in 1872; and these could not therefore, have been taken from 'modifications proposed in England as early as the beginning of 1873.'

I am, therefore, at a loss to know to what instruments Dr. Purves refers. Indeed the only English modifications of ophthalmoscopes for the determination of refraction which were known to me at the time when my paper was written were, first, an instrument made by Smith and Beck in 1869, directly from one of mine, which was furnished by a friend then in England at the request of one of the Surgeons at Moorfields. This instrument was afterwards ex-

hibited at some of our ophthalmological societies by one of the firm then in this country, and somewhat to the edification of the members, as a purely English invention. The second is Dr. Oldham's instrument.* At the International Ophthalmological Congress held in London in 1872, and at which many Americans were present, Dr. Oldham did me the honour, perhaps I might say the justice, to speak of the instrument which he then presented as a modification of my own, which appeared three years earlier. As in his paper, published in the transactions of the Society, my name does not occur, probably Dr. Purves, as well as many others, were under the impression that the instrument there mentioned was a strictly original design. That there is a striking similarity between Dr. Oldham's instrument, that made by Smith and Beck, and my own, cannot be denied; and for this reason I thought that one description, and that the original one, might serve for all three. This seems to me all the more pardonable, as Mr. Carter, in describing my instrument in his late work, appends as an illustration of it a cut made for Dr. Oldham's, which appeared in the transactions of the International Congress in 1872.†

There is, however, one dissimilarity between Dr. Oldham's and my instrument, which is so great as to deserve notice, and that is the size of the mirror hole. This in Dr. Oldham's instrument, as in some others of English make, is so small as to defeat to a great degree the very end for which it was designed, since however well the mirror may illuminate the fundus of the observed eye, but few rays can enter the observer's eye through so small an aperture. The brilliancy of the picture is therefore seriously reduced, and the more, the stronger the curvature of the glass used, if this be negative. But a more serious defect is the action of so small a hole on the real focal value of the glass. For example, with a hole as small as that in Dr. Oldham's ophthalmoscope, $+\frac{1}{36}$ has barely a perceptible effect on parallel rays, and is completely neutralised by $-\frac{1}{96}$. Its real focal value is therefore only one-third of what it is marked on the instrument. So too $+\frac{1}{20}$ is really $+\frac{1}{20}$, and only one half as strong as represented, and so on in a proportionate rate with the whole series of twelve glasses down to $+\frac{1}{5}$, which is the first glass which corresponds with the number given to it on the disk. Precisely the same thing occurs with the negative glasses.

No ophthalmoscope can be made with a silvered mirror, which is not liable to such a disturbance from its action as a diaphragm; but the error can be reduced to a minimum by making the size of the hole equal to 3.75 millimètres in diameter, which is the size of the earlier instruments, and the same as used in my first modification, and which, all things being

* Mr. Couper's Modification, mentioned by Mr. Carter as recently made by Mr. Hawksley, I have not yet seen, but if made so that the obliquity of the mirror is not connected with the disk, it differs from all American instruments, and is open to precisely the same objections that were pointed out years ago in regard to similar ophthalmoscopes, where loss of field of view and illumination is so great as to render their use impracticable with glasses of high power.

† I must here do Dr. Noyes the justice to say that a mistake occurs in Mr. Carter's late work in regard to his instrument. Dr. Noyes's ophthalmoscope is not, as stated and figured in Mr. Carter's book, a modification of mine, but a totally different instrument, designed for office practice, and one to which all the glasses in Noyes's test cases can be fitted at will. It also has a movable mirror.—*Trans. Amer. Ophth. Society, 1870.*

considered, is the best for purposes of illumination and accuracy of measurement.

It follows at once from the above, that it is impossible to determine with an ophthalmoscope, with a mirror hole of $1\frac{3}{4}$ or even of 2 millimètres in diameter, the lighter, or even the moderately strong, errors of refraction with any accuracy; and this may perhaps be the reason why so much doubt exists among English ophthalmologists as to the advantages of the method, and why this whole subject is so inadequately treated even in their latest works. Still, in time, and with suitable instruments, there is no reason why the method by the upright image should not be regarded with the same high appreciation in England that it has been in America for the past ten years.

In regard to the spring for centring the glasses, which would at once suggest itself to the least inventive mind, I would say that it was proposed in this country as early as 1869, and its use dispensed with, because where the mirror-hole is 3.75 millimètres in diameter, reflexions arose from the edges of the canal unless the diameter of the glasses were made disproportionately large, thus increasing unduly the size of the disc. These annoying reflections can be entirely removed in dispensing with the spring by decentring the glass, by moving it a little towards the right or left, as occasion requires.

When, however, the diameter of the glasses was reduced through perfection of optical work to four millimètres, it became necessary to centre the glasses to avoid confusion in bringing them into position.

I still think that the alleged advantage of rotating the disk without taking the instrument from the eye is rather apparent than real, and to those who really wish to do accurate and close work of no use whatever, as there is not room enough between the nose of the patient and the edge of the disk to permit such rotation, if the instrument be held as close to the observed eye as a proper examination demands. As a rule, it is only an aggravation to the patient and to the observer.

For myself, I much prefer the older instrument, with the larger glasses, and a larger mirror-hole. I think also that a shallow cylinder is preferable to a flat disk, because the glasses do not become soiled by handling.

In what I have said I have of course alluded only to ophthalmoscopes, which, however serviceable they may be for all the uses of the instrument, are particularly adapted for that of the upright image.

Hoping to learn from Dr. Purves through your columns, to what instruments he has reference which are described in my pamphlet, and which are of English origin, I remain very respectfully yours,

EDWARD G. LORING.

RECENT FRENCH BOOKS.

Précis élémentaires de l'art des accouchements sous forme de demandes et de réponses, par le docteur C. Girard, professeur d'accouchements, lauréat de la Faculté, ancien interne des hôpitaux, avec figures intercalées dans les textes. Paris, 1876.

MISCELLANY.

M. VULPIAN has been appointed a member of the Council of the Assistance Publique in Paris.

M. LE FORT has been appointed a member of the Paris Academy of Medicine in the section of surgical pathology, in place of M. Demarquay.

LONDON HOSPITAL.—Dr. Charles Meymott Tidy has been appointed lecturer on chemistry at this hospital, vice Dr. Letheby, deceased.

FREE CLINICAL LECTURES.—The free course of clinical lectures, at Birmingham, which are being delivered during the present session at the Children's Hospital, are attended by a class of fifteen students.

CEREBRO-SPINAL MENINGITIS.—Epidemic cerebro-spinal meningitis, unknown here until a year ago, is still prevalent in Birmingham and the district. Most of the sufferers are children or young adults. The disorder varies much in severity and duration, in some instances being fatal in three or four days, in others running a course of several weeks.

MISS JULIA SINCLAIR has just been admitted as Doctor of Medicine at the University of Zürich.

DR. LLEWELYN THOMAS has been appointed Honorary Physician to the Royal Academy of Music, Hanover Square.

NEW SCIENCE COLLEGE.—The erection of Sir Josiah Mason's magnificent Science College is in rapid progress. The site and buildings will cost about 150,000*l.*, while 100,000*l.* are devoted to endowment. A new medical school will probably form a department of the College.

SCIENTIFIC RESEARCH.—It is understood to be in contemplation to increase the grant of 1,000*l.* per annum placed some years ago, on the intervention of Earl Russell, at the disposal of the Council of the Royal Society for scientific researches. The amount proposed to be added will, it is said, be 4,000*l.*

GOING INTO HALF-MOURNING.—In the course of a paper read by Mr. O. C. Stone on 'The Country and Natives of Port Moresby, New Guinea,' at the last meeting of the Royal Geographical Society, he stated that, 'In case of a death, the relatives of the deceased went into mourning by painting their faces with plumbago, and sometimes by wearing armlets composed of the bones of the departed.'

NIGHT MEDICAL SERVICE IN PARIS.—Since Jan. 9 of the current year, the date at which the night medical service of Paris commenced, the services of the medical men who have inscribed their names at the Prefecture, have been called into requisition by 1,180 patients. Out of this large number nine persons only died before the arrival of the medical attendant. A sum of 10 francs, to be reimbursed by the patient if he is able to do so, is allotted for every visit; and as up to the present time the liquidation of the sums advanced has gone on with great regularity, the credit of 10,000 francs appropriated to the service by the Municipal Council is scarcely touched on as yet.

THE EUCALYPTUS GLOBULUS.—The medicinal properties of the *Eucalyptus globulus* formed the subject of an interesting paper read by Dr. Fedeli at the Roman Academy of Medicine on April 30. After adverting to the natural history of the plant, and citing a host of witnesses as to its virtues as a febrifuge, Dr. Fedeli proceeded to describe the curative powers of the various preparations of the *Eucalyptus*, especially of the alcoholic tincture, not only in cases of periodic fever and of palustral cachexia in general, but also in ailments of an atonic or anæmic nature. In the discussion that followed the reading of the paper, Dr. Colapiete ascribed the virtue of *Eucalyptus* in malaria to its cultivation increasing the quantity of ozone in the air; while Drs. Marchi and Terrizi opposed this view, the latter maintaining, as the result of experiments made on bacteria and micrococci, that ozone instead of diminishing actually increases the fermentative action of the malarial poison.

A ROMAN METHOD OF INTERMENT.—An interesting discovery was made in the Roman Cemetery at York last year. A large stone coffin was uncovered, containing another of lead. The lid of this bore a curiously corded pattern impressed upon it. When this lid was removed it was found that the corpse had been laid upon a bed of gypsum, which had also been poured over it, so that a perfect impression of the body was obtained. The head seemed to have been raised originally upon a pillow, so that it was above the gypsum. And here a remarkable sight presented itself. The facial part of the skull had given way, so that the back of the head was precipitated forward, and on it was the long, folded tress of a young Roman lady, with two jet pins, beautifully wrought, remaining in it. The hair had preserved its colour, auburn of several shades; it had kept its smoothness, and was so limp when first exposed to the light that it might have been washed and almost combed. It now constitutes one of the choice treasures of the York Museum, and shows no sign of decay.

AN AUTOPSY AT THE HÔTEL DIEU.—The *Academy* describes a picture by M. Gerves, now exhibiting in the Paris Salon. It is called 'Une Autopsie à l'Hôtel Dieu,' and is described as follows by our contemporary. 'The circular table covered with its white linen cloth stands in the centre, under the vaulted roof of a thick-walled room. The rise of one great arch is seen near the centre springing towards the left, and through loop-holes cut on each side of it shoot rays of light which fall on the emaciated corpse which lies on the table, and on the group which surrounds it. At the head, on the right, stands the attendant, his cap drawn over his eyes, his blue sleeves rolled up to the elbow; indifferent and business-like, he steadies the table with both hands, whilst the young fair-haired surgeon, unconscious, calm, intelligent, animated with the divine curiosity of science, proceeds with his work. The scalpel rests on the inner side of the right thigh, and the exquisite delicacy of a practised touch is observed and rendered with consummate truth. Between these two figures stands a third, a medical student, and his attitude, which expresses neither the indifference of the attendant, nor the dignified inquiry of the master—a little conscious, a little bold, yet really interested (his hand nervously repeat the movements which he watches)—is finely discriminated. The white of the broad sheet which covers the table on which the body lies is further massed by the customary white bib-aprons worn alike by those who operate and those who assist, and the tone of the flesh has been delicately felt in relation to it; everywhere the relative values of each varying tint are so just that they speak of a steady habit of exact and patient observation, and the quality of light which has been thus obtained is so real in effect that the air seems to pass vibrating through the picture.'

PROVISION FOR SICKNESS AT THE PHILADELPHIA EXHIBITION.—On this subject the *Boston Medical and Surgical Journal* of May 18 writes: 'The hospital of the centennial exposition, which was to have been one hundred feet long, has been reduced to sixty, and some of the conveniences which would have made the building more comfortable during the hot months have been set aside because of lack of funds. The commission are now 1,500,000 *dols.* in debt, notwithstanding the 1,500,000 *dols.* voted by Congress. This deficit will undoubtedly be more than covered by the entrance fees. Ten thousand dollars per diem for 180 days (the duration of the exhibition) will put 1,800,000 *dols.* into the treasury of the commission. The anticipation is that far more than 20,000 persons will visit the exposition daily during its continuance. It may be that additional hospital conveniences will be erected so soon as the authorities realise, as they undoubtedly will, that there will be more extended calls upon the officers of the medical service than they are now inclined to believe. There will be a male and a female ward, but no provision has been made for a class of cases which will be certain to be well represented, namely, confinement cases. Statistics show that during the Paris exposition there were 780 cases of labour on the grounds. Summer weather in Philadelphia is so much more intense than that to which many who will attend the exhibition are accustomed, that the effects of heat, together with the great fatigue incident upon the work of visiting merely the principal buildings, will be certain in many cases to bring on labour. There are already 3,000 individuals who are living on the grounds. They make constant calls upon the resident physician. The probable additional cases of sickness during the exposition will give busy hours to the other officers of the medical service. It is anticipated that the most trying cases will be those of sunstroke. As many as twenty-seven persons in one day have been carried to the Pennsylvania Hospital alone during past summers. In the largest buildings of the exposition the temperature is much lower than that of the outer air, but it will be in wandering from one building to another that visitors will especially feel the effects of the tropical weather in Philadelphia.'

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

LEBERT ON THE VARIOUS FORMS OF ANÆMIA, AND THEIR TREATMENT.

The April number of the *Archives Générales de Médecine* contains an article by Professor H. Lebert on the varieties of anæmia or dysæmia, with especial reference to the form which he calls essential or idiopathic. It is an expansion of the chapter on this subject in his Handbook of General Pathology and Therapeutics, of which he has recently published a new edition in Germany.* He objects to the term 'oligocythæmia' as expressing but a very small portion of the truth, for anæmia is much more than a mere diminution of the red corpuscles. The composition of the blood is altered, though as yet chemistry has told us but little of the changes; the distribution of the blood is altered, and so is the innervation of the vascular system. Dysæmia would be a far better term, but he retains the old name of anæmia, as generally known and adopted. We may distinguish different forms by such terms as 'spoliative,' when it results from losses of blood, or of lymph, or of any secretions or excretions; 'in-anitive,' when it arises from insufficient nourishment; 'destructive' (*consumptive*), when the elements of the blood are consumed faster than they can be made, as in fevers of long duration; there is a dystrophic form when nutrition is profoundly altered, as in cancerous affections, tubercular diseases, chronic nephritis of different kinds, and forms of chronic poisoning. Anæmia may be termed 'neurotic,' when it results from a modified action of the nerves on the circulation and formation of the blood, as in chlorosis and essential or idiopathic anæmia.

Except as regards the lessened number of red corpuscles, organic chemistry has taught us but little of the changes in the blood in anæmia. No doubt there are difficulties in the way of analysis; and for one thing, anæmic patients can ill support the venæsection which would be required in order to analyse their blood. As regards the red corpuscles, there are slight forms in which they vary between 110 and 100 per 1,000, and a more severe form in which they are lessened to 65 per 1,000 (Andral), or even less. Andral and Gavarret mention even as few as 28 per 1,000 in human beings; and in sheep they have seen as few as 15 per 1,000 parts.

In average cases it is rare to find the red corpuscles diminished below half the normal number, except perhaps temporarily after very large and sudden losses of blood. The buffy coat met with in such cases is no proof of inflammation; on the contrary, it increases just in proportion to the poverty of

the blood. This was pointed out by Burserius long ago. Lebert does not approve of any distinction, being made between acute and chronic cases, for he has seen the one pass into the other. At present we have two great categories of cases of anæmia: one class, of which the causes are well known and quite definite; another class in which the causes are only known very imperfectly, or remain quite unknown. To the first class belong the spoliative anæmias, whose causes and symptoms are easily recognised. Amongst these we have losses of blood, losses of lymph, and loss from excessive and prolonged secretions or excretions. Anæmia from starvation also falls into this category, and then we may include the cases in which there is a consumption of the elements of the blood more rapid than their production, as in febrile diseases of long standing.

Amongst the forms of anæmia whose causes are either known imperfectly or are quite unknown, we must include chlorosis and essential or idiopathic anæmia, and perhaps also the forms of anæmia, in which there is cachexia. Class I. includes the impoverishment and alteration of the blood from definite causes, and Order I. spoliative anæmia, with diminution of corpuscles.

a. *Anæmia from Lymphorrhage, or Excessive Flow of Lymph.* Professor Lebert has described the dilated condition of lymphatic vessels, their varices, and the excessive flow of lymph in some cases in Virchow's Pathology (Virchow, *Pathologie et Thérapeutique Spéciales*, 2nd ed. vol. v. p. 666). He has seen cases in which it was possible, by pricking one of these varices, to obtain a small continuous jet of lymph—and thus to study the character of this fluid. These lymphorrhœas or lymphorrhages may occur spontaneously and repeatedly, and on each occasion such quantities of lymph may be poured out that great and severe anæmia may be the result. One of Fetzner's female patients lost at one time $3\frac{1}{2}$ large glasses of lymph, or about 1,750 grammes, or nearly 57 ounces. Lebert observed a loss of this kind, which lasted nine hours. In a case of Desjardins', frequent losses of lymph lasted ten or twelve hours each time, and on one occasion for forty-eight hours. Whilst a student, Lebert saw a curious case of this kind, in the summer of 1833 in Schönlein's wards. The patient had every six weeks a loss of lymph from varicose lymphatics in the scrotum, which furnished on each occasion some 500 grammes, or nearly 18 ounces of lymph. From this he became pale and anæmic. This loss of lymph had been mistaken for an abnormal secretion of milk. Lebert discusses the symptoms in this form, and shows that they are analogous to those produced by hæmorrhage—especially hæmorrhages from the uterus.

b. *Anæmia from Hæmorrhage or Loss of Blood.* As this form is familiar to English readers, we need not follow him in the details of this class. The concluding paragraph is, however, worthy of note. He points out that there is a class of case, in which, either from the spontaneous cessation of the hæmorrhages or from their cure by surgical means, as for example in piles, and uterine polypi (myomata), the patients appear to be perfectly cured, after very large losses, and do indeed regain the external appearances of health, if looked at carelessly, but when we study them more closely, we find them remain for many years still feeble, easily fatigued, irritable, and an easy prey to disease of various kinds. Lebert's second order of spoliative anæmia from loss of se-

* Lebert: *Handbuch der allgemeinen Pathologie und Therapie als Einleitung in das Klinische Studium und die ärztliche Praxis*. 2e ed. Tübingen. 1876.

cretion, by albuminuria, etc., including as it does anæmia from excessive secretion of milk, which he thinks rare; loss of albuminous fluids in chronic diarrhœas, and loss of albumen in the urine, prolonged sweating, prolonged suppuration, and the like, may also be dismissed, as familiar to English medical men.

c. Anæmia from Insufficient Nourishment or Starvation.—His remarks on this head are founded chiefly on the observations of Chossat, C. Schmidt, and Voit. He remarks with truth that schools, prisons, workhouses, and other public institutions afford a large field of study, in regard to this variety, to the practitioners of medicine. So do those diseases which cause dysphagia, whether they are the result of accident, as when caustics are swallowed, or proceed from cancer, tumours, or other morbid conditions. Cases of refusal to swallow food, of indigestion, and the like, are next discussed. Cases of cancer and canceroid tumours of the œsophagus, are complicated by the cachectic effects of the malady on the general system. So again, in phthisical ulcerations of the epiglottis, the effort to swallow is followed by regurgitation, and the patient is thus discouraged and hastens his own end by inanition. Cases of chronic poisoning by lead, mercury, and arsenic, are somewhat obscure as regards the etiology of their anæmia. The poison seems to attack the very sources of blood-formation, and of these we really know very little. Can we say that we know more about the causes of poisoning by marsh-miasmata? Lebert thinks not, for it exceeds what we might reasonably expect from the disordered digestion, and the disappearance of a certain number of red corpuscles in the spleen and the subsequent melanæmia do not sufficiently explain it. The anæmia consequent on disease of the heart and great vessels may be a trifle plainer, but is still obscure. Nor does chronic alcoholism appear to owe its anæmia to the effects of alcohol on the digestive organs alone. However, it is worthy of note that the anæmia in cases of chronic alcoholism is never so great as we observe in many other morbid states, for example, in cases of cancer.

Class II. Includes impoverishment of the blood from unknown causes. Under this heading we get chlorosis, and essential or idiopathic anæmia.

a. Chlorosis. People fancy they know all about this, because they are content to define it as a diminution of the red corpuscles, and of the iron in the blood. It was surely a happy instinct which led physicians to call this disease chlorosis, rather than anæmia. Almost all pathologists now admit the nervous element in these cases. There is no direct proportion between the percentage of the blood-discs and the functional troubles of chlorosis. Moreover, it often seems to arise when the hygienic conditions are favourable, and is by no means confined to the poor. Causes of spoliation are usually absent. We must therefore conclude that the formation of the blood is at fault. Why, we know not. Possibly the white corpuscles are formed in less quantity, or they are not transformed into red ones. We talk of nervous influence, but the real nature of this is unknown. The relative smallness of the heart and great vessels, invoked by Virchow, may apply to certain cases, but scarcely to the numerous and happy instances of cure which we see. What a strange state of anæmia is that, in which we see our patients pale and feeble and out of breath after some trifling exertion, yet able to dance

half the night without serious harm, or take long walks when the excitements of pleasure and contentment come to their aid! It is doubtful whether iron really effects most of the cures. Ferruginous mineral waters are, no doubt, useful; but there are other ingredients. Quinine and arsenic appear of great service in the neuralgic forms. Hygienic and moral treatment—or, as Lebert well puts it, both physical and moral hygiene—are as necessary as drugs, or even more so, in the treatment of chlorosis.

b. Essential or Idiopathic Anæmia.—Lebert prefers this name to that of 'progressive pernicious anæmia,' under which Biermer,* Gusserow,† Ponfick,‡ and Zimmermann§ have described this disease. Essential simply implies that the causes are unknown. The more he studies the disease, the more difficult does it appear to be to find a common cause. Biermer and others have maintained fatty degeneration of the heart as the common property of such cases. But it was only present in two out of three of our author's fatal cases, and cases equally serious have ended in recovery. Fatty heart, again, may be present without this severe form of anæmia. Further, he objects, so long, at least, as the recorded number of facts is small, to include a prognosis in the appellation of the disease.

The proclivity or preference of this form of anæmia for pregnant or recently delivered women was first observed by Lebert in 1853. He vindicates his claim to priority, or at least very early publication, by referring to the published reports of the medical department of the canton of Zürich for 1853,|| and from a French journal¶ he quotes the following *verbatim*. 'We have three times observed a peculiar chlorotic condition, hitherto undescribed—acute, febrile, and supervening quickly after delivery. The absence of any definite organic lesion, and the presence, on the other hand, of the clearest symptoms of chlorosis in women who have scarcely lost any blood at all in their labour or after it, cause us to look on this condition as a chlorosis due to the puerperal condition. One of our patients had general anasarca, without any albuminuria, and without any signs of Bright's disease. These three women all got well in from three to six weeks, under treatment by tincture of malate of iron, of which thirty to fifty drops were taken thrice daily.' In the German text he called it 'acute puerperal chlorosis,' but he admits that 'acute' is an ill-chosen term, because this condition appears to be developed during the pregnancy in some cases. Brief notes are given of these three cases. One was a woman, aged thirty-three, in good health till her fifth pregnancy. During this she had slight symptoms of anæmia. A few days after delivery (in which she lost hardly any blood, and the labour itself was natural) alarming symptoms of severe anæmia set in. When admitted to hospital, sixteen days after the birth of the child,

¶ Lebert: 'Résumé des Maladies observées dans la division de clinique médicale de l'hôpital de Zurich pendant l'année 1853,' p. 14. *Gaz. Méd. de Paris*. Année, 1854.

there were no signs of organic disease, but she had a quick pulse, hot skin, and a hæmic bruit. The urine (s. g. 1017) appeared perfectly normal. For many weeks she remained in a restless, sleepless, and dangerous condition, spite of all treatment. But after rather more than two months she improved, and left the hospital in another month greatly better. There is in these cases a real rise of temperature, not easy to account for. Lebert notes the same in several cases of hæmatemesis, in which the temperature long remained above 99.5° Fahr., and even above 100.4° Fahr. The second case, in 1853, of this anæmia was in a pluripara, aged twenty-nine, a cotton-spinner. Her symptoms began in the third month of her third pregnancy, but were not alarming till three or four weeks after apparently natural labour, without hæmorrhage. Her state continued alarming till nearly three months had elapsed. After observing three more cases, in 1854, Lebert again drew attention to these cases in his reports of the medical department for that year. Again he published a fatal case in the *Wiener Medicinische Wochenschrift* (1858, no. 34 'Ueber essentielle Anämie.') This patient was only aged twenty-four. She had been married five years. She had had one child before, and the last labour, ten weeks before admission to hospital, was apparently quite normal. The lochia were rather scanty. There were, however, several attacks of epistaxis, short, and of no great severity, yet they seemed to greatly exhaust her. There were no signs of organic disease. She had a quick pulse (108-120); rapid breathing; hot, dry skin; extreme pallor of skin and mucous membranes, and all the rational signs of extreme anæmia, including the usual nervous symptoms. In spite of all treatment, she died fifteen weeks after her labour, in most complete collapse. All the viscera, even the brain, were extremely anæmic; the blood in the cerebral vessels, and indeed everywhere, was paler than it should be (pale red, or pale brown). The large vessels everywhere were nearly empty. There were scarcely any clots or blood in them, or in the heart. The liver was somewhat enlarged. The heart's substance was pale and soft (fatty?) Other cases are reported by Lebert in his reports for 1867, and in the Vienna journal quoted above. In a male patient, aged forty-five, a linen-weaver, the necropsy showed extreme anæmia of all the organs, some leucine and tyrosine in the lungs, and in the liver, which was slightly fatty. The heart's structure was healthy. The kidneys contained some inosite.

In a fatal case in a woman, aged fifty-five, besides extreme anæmia of all the organs, there was some fatty degeneration of the heart (and liver also), and the aortic valves were a little atheromatous. There was fluid in the pericardium, in both pleuræ, and in the peritoneal cavity.

The favourite age in the female is twenty to thirty years, but one woman, just mentioned, was fifty-five. The three men were aged thirty-nine, forty-four, and fifty years respectively.

Lebert thinks it not unlikely that there is a special neurosis of the great sympathetic, like the tachycardia exophthalmica of Basedow (Graves's or Begbie's disease). But at present this is mere theory. In remarking on the treatment of anæmia and its causes, Lebert insists on the folly of adopting roundabout and antiquated methods of stopping hæmorrhage, when we can do this by direct methods such as the ligation of arteries, or the removal of tumours or similar methods. He inveighs against the 'diète absolue,'

more common in foreign hospitals than in our own; he insists on the importance of artificial feeding in some cases, of rest, of change of air, the use of quinine (of which he prefers the muriate), arsenic, iron, especially the malate or pomate, of change of air, of cheerful society, and sometimes of good wine. In young females, he gives baths, and even bromide of potassium; in many cases of dyspepsia and chlorosis he finds alkaline and effervescent waters of use. A mixed diet is essential and scientific. Moral treatment in many cases is more appropriate than the rage for restoring iron to the blood.

W. BATHURST WOODMAN.

OSTROUMOFF ON THE INHIBITORY NERVES OF THE CUTANEOUS VESSELS.*

A. Ostroumoff has investigated the above subject in the laboratory of Professor Heidenhain of Breslau. By the term 'inhibitory nerve' the author means a nerve whose action is to diminish the activity of other nervous apparatus, and this the more, the more energetically it acts. An inverse relation exists between the degree of activity of the inhibitory nerves and that of the inhibited nervous apparatus. The author has sought to determine the condition of the cutaneous vessels by measuring the temperature of the skin. The animal employed was the dog, and the temperature was taken by very sensitive thermometers placed on the interdigital membrane of the foot.

1. *Stimulation of the freshly divided Sciatic Nerve by means of Tetanising Induction-Shocks.*—In order to prevent evaporation and drying of the nerve, its peripheral end was placed in a T-shaped glass tube, into the vertical stem of which electrodes in connection with the secondary spiral of the induction machine were placed. Stimulation of the peripheral end of the nerve was always followed by a contraction of the vessels, which was not temporary, as indicated by Goltz (LONDON MEDICAL RECORD, January 1876), but lasted for a long time, so that there was not a rapid exhaustion of the nerves which produce contraction. The reason of the difference in Goltz's experiments is to be sought in the fact that Goltz stimulated the nerve several days after it had been divided, i.e. when degeneration of the nerve-fibres and loss of excitability had already taken place.

2. *Tetanic Stimulation of the Sciatic Nerve three or four days after Section.*—In this case, tetanic stimulation was followed by a rapid increase of temperature. The result depends upon the time after section. After six days, no result could be obtained.

3. *Stimulation of the freshly divided Sciatic Nerve by means of single Induction-Shocks.*—Induction-shocks applied at intervals of five seconds produced an increase of temperature, which could also be produced, though more rarely, by tetanisation by very weak currents. From these experiments the author concludes that the sciatic nerve contains the proper vaso-motor fibres, whose stimulation causes contraction of the vessels, together with inhibitory fibres whose stimulation is followed by dilatation of the vessels. If the normal nerve-trunk be stimulated with single induction-shocks of the proper strength at regular intervals of five seconds duration, the influence of the inhibitory fibres is exerted; if the nerve

* *Pflüger's Archiv*, Band xii. p. 219.

be tetanised, and the currents do not lie between very limited and very small values, the effect of the vaso-motor fibres is the more pronounced.

After section of the nerve-trunk, the excitability of the vaso-motor fibres sinks more rapidly than that of the inhibitory fibres, so that during a certain period after section (three or four days) the excitability of vaso-motor fibres is nearly extinguished. At this time tetanic stimulation, because it acts on the still highly excitable inhibitory nerves, in opposition to the results on the normal nerve, no longer produces contraction, but dilatation of the vessels. The author believes in the existence of peripheral ganglionic apparatus placed in connection with the vessels. The tonus of the vessels depends upon the great nerve-centres and also upon these peripheral centres, on which two kinds of nerves act—the vaso-motor, by increasing their activity; the inhibitory, by diminishing it. The dilatation of the vessels, following section of the nerve, lasts very much longer than the excitability of the divided nerve itself. The dilatation also in the course of time diminishes, but it never completely disappears. The inhibitory apparatus of the cutaneous vessels is more like that of the salivary glands than that of the heart. The inhibitory nerves of the cutaneous vessels, like those of the chorda tympani, are not affected by a much larger amount of atropin than suffices to paralyse the inhibitory fibres of the vagus, and the secreting fibres of the chorda tympani. The blood-vessels whose vaso-motor nerves are divided, can no longer be regarded as simple elastic tubes, whose diameter is determined alone by the pressure exerted upon their inner surface. Very pronounced increase of the blood-pressure has no obvious dilating effect on the small arteries and capillaries. The pressure within the aorta may be doubled without the temperature of the skin being increased. Such vessels with divided nerves do not, however, conduct themselves exactly like quite normal ones. The capacity of the former to resist fatiguing influences is much more easily exhausted. In the author's experiments, the increase of the blood-pressure was produced by stimulating the peripheral end of the great splanchnic. The temperature rose as little in the paralysed as in the normal limb. The activity of the vascular wall therefore must be independent of the nerves passing to it from without. If the sciatic nerve of the paralysed side have been previously stimulated, the increase of the blood-pressure produced by stimulation of the splanchnic has a decided effect upon the temperature. It is therefore proved that : 1st. The blood-vessels, even after division of their nerves, offer great resistance for a long time to the dilating action of the blood-pressure when suddenly increased ; 2nd. This capacity for resistance is diminished by fatiguing influences ; 3rd. Vessels which are still in connection with the central organs are much more capable of developing this resistance, because they are less easily fatigued.

It is therefore probable that the peripheral end organs of the vaso-motor nerves exercise a regulating influence on the blood stream.

The inhibitory nerves of the cutaneous vessels may be set in action by reflex stimulation. Heidenhain has already shown that stimulation of the central end of a sensory nerve increases the temperature of the skin. Owsjanniskow has shown the same for the inhibitory fibres of the chorda tympani; and Goltz observed that the foot of the other side became normal on stimulating the central end of the sciatic

nerve of the other leg in a dog, whose spinal cord had been divided at the last dorsal vertebra. This dilatation of the vessels was here also undoubtedly reflex, as is shown by the author.

Stimulation by suspension of the respiration increases the temperature of the skin (Heidenhain); but blood-vessels whose nerves are divided are not so affected. If, however, the peripheral centra have been exhausted, the increase of pressure produced by suspension of the respiration causes dilatation, but not on vessels with active motor apparatus. The inhibitory nerves may also be excited by nicotin, and by psychical stimuli.

On the Course of the Vaso-motor Nerves from the Central Organs to the Sciatic Nerves.—The author confirms the opinion of Claude Bernard, that the vaso-motor nerves avoid the paths from which the sciatic nerve receives its motor and sensory fibres (sacral plexus) and rise higher up, reaching the sciatic through the sympathetic. Both the vaso-motor and the inhibitory nerves reach the sciatic through the abdominal sympathetic.

1. Section of the sacral roots and their stimulation have both no appreciable direct influence on the temperature of the hind feet.

2. Section of the sympathetic, on the contrary, at the level of the bifurcation of the aorta increases the temperature permanently.

3. Tetanic stimulation diminishes it.

4. Under favourable circumstances, rhythmical stimulation causes an increase.

5. Sensory stimulation, injection of nicotin, suspension of the respiration, produce an increase of temperature in the hind foot, even after section of the sacral roots; and this to the same extent as in the normal condition, but no longer after section of the abdominal sympathetic (as low down as possible) even when the sacral roots are intact.

The vaso-motor nerves supplied to the sympathetic are derived not only from the lumbar, but also from the dorsal region, though how far up the author has not tested.

W. STIRLING, D.Sc., M.D.

GOURAUD ON THE ACTION OF CLIMATES ON THE TREATMENT OF PULMONARY PHTHISIS.

In a second note on the action of different climates on the treatment of pulmonary phthisis (*L'Union Médicale*) Dr. H. Gouraud says :

If we merely desired to discover the places on the face of the earth where phthisis is absent or rare, the task would be comparatively simple. They are to be found from the stations of Southern France and of Italy, even to Norway, the Faroe Islands, and Iceland; from mild humid insular stations to the steppes of the Kirgoi with their eminently dry climate.

Norway, Iceland, and the Faroe Islands have cold humid climates, and yet appear to enjoy an immunity from phthisis. On the other hand, the cold and dry steppes are now much employed in combination with the use of koumiss. Patients are sent in forty hours by rail from St. Petersburg to Nijni-Novgorod, and from that place to Samara in the steppes, in twenty hours by steamer. There they stay from May 1 to October 1.

What greater contrast can there be, than that between the steppes of Russia, the south of France, and the climate of Madeira? Yet all are sought for

the same object. Granting that many of these places enjoy a considerable degree of immunity from phthisis, why does this immunity not extend to visitors? The answer is, because phthisis is not a product simply of climate. It is also a social disease. If there be any fact certain it is this, that the more people become crowded together, the more industries are developed, the more does phthisis show itself. Crowding in small rooms at home, too early labour, the inhaling of foul air or of deleterious particles in manufactories, a too sedentary life, are frequent causes of phthisis. The great centres of industry are the places which yield the highest mortality from it, as London, Manchester, Liverpool, Paris, Glasgow, New York, Philadelphia, New Orleans, Berlin, Munich, and Vienna. England has been called the home of industry and of phthisis.

We need not inquire here into the accidental and constitutional cause of phthisis; but we may say that, as climate is not the sole cause of phthisis, so climate alone will not produce immunity from it. Phthisis is produced in a great variety of climates, and consequently it is not to be always avoided by the mere selection of a climate.

In medicine climate is an adjuvant, not a specific. The absence of a particular malady from a place does not prove that the place is a prophylactic against that malady. A climate may have tonic and exciting properties which favour the nutrition and the good health of persons born in that climate, and employing a diet and mode of life suitable to it. Yet these same tonic and exciting qualities may not suit subjects already attacked by such and such maladies, and having irritable or vulnerable organs. These qualities favourable to the one class may be unfavourable to the other. The immunity of the natives of a place from any particular disease therefore only furnishes a reason for studying it in its climatic relations.

Immunity of itself affords no guarantee for patients; but if it is proved that there are fewer sick of a given malady, say at a certain elevation, this fact is so far favourable to altitude. If, further, it is verified by direct observation that patients in such or such stages of their complaints derive benefit from residing in the mountains, this is enough to recommend mountains, especially if they have already tried other climates without advantage.

It seems now to be generally admitted that the number of cases of phthisis diminishes as the elevation increases. How is this to be explained? We must in the first place allow that many of the factors of phthisis are absent at a certain elevation, that is, all of them that are connected with social life and aggregation; but besides this, what further explanation have we?

1. Hirsch says that it is because the alternations of temperature are less marked in the mountains than in the plains.

2. Brehmer says that the air is more tonic and favourable to nutrition.

3. Jourdanet says that the cause is the deficient supply of oxygen.

It is true that the relative proportions of oxygen (21), and of nitrogen (79), are the same in the mountains and in the plains, but as the higher layers of the air have less density, the quantity of oxygen in them for each inspiration is less. Experiments have shown that the quantity of oxygen in a litre of air at the height of 15,000 feet is about one-half what it is in the plains. The result of this is that, in order to get the

necessary supply of oxygen, the inspirations become deeper and more complete, and that the thoracic cavity increases in capacity. The pulmonary cells, dilated and enlarged, become to a certain degree emphysematous, and in the end produce the dyspnoea called *asthma montanum*.

Two pathological facts appear in the mountains, which stand in relation to each other, the rarity of pulmonary phthisis and the frequency of emphysema. It seems also probable that the increased expansion of the pulmonary cells leads to a certain degree of anæmia of the lungs, and this anæmia, like emphysema, is considered to be antagonistic to tuberculosis.

The diminution of atmospheric pressure causes a derivation from the centre to the circumference, and produces a real revulsion towards the cutaneous surface. Add to this the tonic action of the air and its influence in promoting appetite and digestion, and we see some explanation of the rarity of phthisis in mountain climates.

To these causes Lombard adds a certain excess of carbon in the system, consequent on the diminished supply of oxygen, and he thinks that this has something in common with the state induced in islanders (who enjoy immunity from phthisis) by the free use of oils and animal fats or butter.

To these influences Lombard adds the effects of hydro-therapeutic treatment and of muscular exercise at the mountain sanatoria, along with the use of wine and fruit and nutritious diet.

Besides other objections that may be raised to Lombard's views, it is difficult to suppose that this real or supposed anæmia is a prophylactic of phthisis in the mountains, when we so often in the plains see anæmia to be a prelude of tuberculosis.

In the place of Dr. Lombard's anæmia, Dr. Gouraud would prefer to assign more satisfactory reasons for the beneficial effects of mountain climates in phthisis.

The purity of the air of mountains consists practically in the absence of all organic particles; and when we consider the effect of vitiated air in crowded workshops in producing phthisis, we can understand the prophylactic effect of mountain air. The transparency of the air which is dependent on its greater dryness, and the more powerful action of light, depending upon the same cause, aid materially the operation of the purity of the air. The effect of residence in mountains on the dimensions of the chest is also worthy of careful consideration, and has been studied by M. Armieux, at Barèges, at a height of more than 3,000 feet. He ascertained that in the case of ninety-six soldiers who were sent up to Barèges there was, after four months residence there, a distinct increase in the measurement of the chest. If this result be fully established, it is evident that it will have a very important bearing on cases of threatened phthisis in the young, and that a mountain climate is to be considered as favourable to the development of the thoracic cavity, and consequently as improving the respiration.

We thus understand how mountain air may be useful in certain cases and in certain periods of phthisis. It acts by its purity, by its dryness and transparency, as well as by the diminution of atmospheric pressure. Dr. Gouraud observes that these principles have only, or nearly only, been applied in Switzerland, and thinks that mountain stations for such cases might very well be selected in some parts of France.

He concludes by observing that after all neither barometer nor thermometer, neither hygrometer nor anemometer, can determine what is the suitable climate for such and such a phthisical patient. All depends on the nature of his constitution, and on the way in which the various meteorological conditions affect him.

J. MACPHERSON, M.D.

BARKER ON UNUSUAL UTERINE HÆMORRHAGES.

The following remarks were made at a meeting of the New York Academy of Medicine by Dr. Fordyce Barker (*New York Medical Record*, January 29).

There is a class of cases in which uterine hæmorrhage occurs independently of any peculiar condition of the uterus itself. Certain conditions of the ovaries may give rise to an unusual discharge of blood from the uterine cavity.

Acute ovaritis is one of these conditions; and although very rare in the non-puerperal woman, yet under the influence of strong sexual excitement, or by some sudden shock, emotional or physical, the process of ovulation is arrested, acute ovaritis is excited, an increased fluxion of blood towards the uterus is developed, and profuse hæmorrhage may follow.

Ovarian dysmenorrhœa is another condition which is sometimes attended by profuse uterine hæmorrhage, although deficient menstrual discharge is more frequent. There is what has been termed the ovarian temperament, a condition in which the ovarian function is very active, fully completed, while the uterine function and development are correspondingly imperfect. This class of cases is characterised by the early appearance of menstruation, by an excitable nervous temperament, a tendency to hysteria; and when menstruation is to appear, the function will be preceded for two or three days, or even more, by languor, nausea, headache, pains in the breast, and frequently by severe pains in the region of the ovaries; and when at last the menstrual discharge appears, in a certain although not large percentage of cases it is apt to be excessive. These cases of ovarian dysmenorrhœa and menorrhagia are not very rare. In some instances great benefit is derived from the use of bromide of potassium, administered in free doses for a few days previously to the occurrence of menstruation; and to this may be added leeching at the commencement of the ovarian symptoms. Of course, the woman should maintain the most perfect quiet and rest in the recumbent posture during the entire time occupied by each menstrual epoch.

Sometimes the shock developed in this class of cases will be such as to require an entirely opposite course of treatment. Here again the plan to be pursued is determined by the general condition of the system; and if there is a depressed condition present, it must be met by the use of those agents well recognised as being proper and important in the treatment of shock and depression under any circumstances.

Both plethoric and anæmic conditions of the system are found associated with ovarian dysmenorrhœa and menorrhagia.

Acute ovarian displacements, such as a sudden prolapsus of an ovary from violent effort, or shock, or produced by constipation, may give rise to menorrhagia, as a result of the highly congested ovary. When this accident occurs it will be attended by

acute symptoms of displacement of the ovary; and the patient suffers greatly from the characteristic pains which attend this displacement, and the condition may be accompanied by menorrhagia extending over two or three menstrual periods. As a matter of course, the rational method of treatment under these circumstances is to overcome the displacement and the ovarian congestion.

There is another class of cases in which both menorrhagia and metrorrhagia occur, which are due to conditions of organs remote from the uterus, or constitutional causes, if you choose to call them such.

Profuse hæmorrhage from the uterus may result from obstructed portal circulation, obstructed circulation through the right cavities of the heart, and also from certain diseases of the kidneys.

Disturbed brain-action from emotional causes may be followed by violent uterine hæmorrhage. Such cases must have fallen under the clinical observation of most who have been long in practice, which are entirely unassociated with any evidence of local affections of the uterus.

Again, we have constitutional causes of uterine hæmorrhage, which may be regarded as toxic.

Malaria is not unfrequently the cause of menorrhagia, not always profuse, but the menstrual flow is prolonged unduly by the general impairment of the constitution and the defective nutrition of the blood-vessels of the uterus from the continued influence of malaria.

Menorrhagia may be caused by the toxic influence of various exanthemata. A most remarkable case of menorrhagia once came under my observation, and occurred in the person of a girl, aged eleven years, who was suffering from measles. The exhaustion present in that case was equal to anything I ever saw in the adult female, having profuse uterine hæmorrhage from any other cause. It was finally arrested, after a great variety of measures adopted had failed, by the introduction of an alum cone into the cervix. This is the only case I have ever seen in connection with measles.

I have seen four cases of this character occurring in patients sick with scarlet fever. It is also said to occur with typhoid fever, small-pox, yellow fever, etc.; but associated with these latter, menorrhagia has never fallen under my observation.

There is another class of cases in which excessive uterine hæmorrhage occurs, dependent upon a constitutional cause somewhat peculiar. Perhaps I am wrong in classing these cases under a constitutional head; but the class of cases to which I refer may be described as follows. A woman who has been free from any uterine disease, perhaps has borne one or two children, suddenly begins to grow stout, and exhibits a remarkable tendency to obesity; so that from being a thin, spare woman, she increases in weight from fifteen to fifty pounds, or even more, and with this remarkable tendency to obesity there is in some cases a rapid diminution in the amount of blood lost at each menstrual period.

But there are other cases belonging to the same class, where, instead of diminution in the menstrual discharge, this tendency to obesity is accompanied by an excessive uterine hæmorrhage. These are troublesome cases, for the reason that you will suspect, from the severity of the flow, some serious uterine lesion; but when you come to make the most careful examination, you will be rewarded by a failure to detect any condition which will satisfactorily ex-

plain the occurrence of the hæmorrhage. The only thing which does explain the hæmorrhage in these cases, is the increased size and consequent plethora of the uterus.

I think that cases of this class are not very rare. I have repeatedly examined the internal surface of the uterus, after dilating the cervix with compressed sponge, in these cases, feeling certain that I should find some uterine disease which would account for the profuse flow, but have been disappointed in the same number of cases by finding it entirely free from any lesion or disease appreciable or discoverable by the most careful examination. The appearance of these patients is usually healthy, and the countenance is commonly flushed, but at the same time they are anæmic. The blood is impoverished, and the patient has a flushed face simply because the capillaries upon the surface, which are not large enough to allow blood of a normal character to pass through them, now carry red anæmic blood, and the slightest emotion or exercise causes them to be surcharged and the face to become flushed. They are cases of anæmia, and when placed upon the use of tonics, quinine, iron, chlorate of potassa, etc., instead of becoming stouter and increasing in weight, they will diminish in size and weight, while the patient is greatly improved in health and strength. It has seemed to me also that there are certain moral phenomena peculiar to this class of cases, for these patients almost invariably believe that they are suffering from some disease of the heart. They are especially liable to attacks of palpitation, and a very frequent complaint will be, that they have awoke in the night and found that the heart has stopped beating.

The plan of treatment which I adopt for these cases is first to administer the acetate of ammonia and saline cathartics, for the purpose of depleting the blood of its excess of watery elements. Next, I use chlorate of potash as an agent of very great value, on account of the influence it has in changing the condition of the blood; and then come the preparations of iron.

In immediate association with this class of cases comes another form of menorrhagia, namely, chlorotic menorrhagia. We may have chlorotic menorrhagia as well as chlorotic amenorrhœa, although it is not of such frequent occurrence. These cases, however, are sufficiently frequent to be met with by any man with an ordinary amount of practice.

Another class of cases, with which every practitioner must constantly come into contact, is menorrhagia associated with the climacteric period. These form a class of troublesome cases. For some reason the menstrual function becomes more active than natural, and is sometimes prolonged as to duration, and abnormal as to frequency of recurrence. Many of these cases occur in women who, at the period of the menopause, have a tendency to become much more corpulent than in former life, and in some such the menorrhagia may be conservative in relieving dangerous plethora, but it is by no means confined to this class. It is also seen in the thin and spare. When it occurs, it usually excites great apprehension in the mind of the patient, for, with a great majority of women, the belief is strong that the time of the menopause is the time of all others most favourable for the development of malignant disease of the uterus, which will destroy their lives.

And it is only natural that we should expect to find some uterine lesion present, when we take into

consideration the changes which this organ has undergone during a series of years. The mucous membrane has been constantly undergoing change, sometimes in the full development of the decidua of pregnancy, and certainly in the formation of the menstrual decidua. It is not surprising, then, that at this period a recurring physiological congestion should in some cases become a chronic engorgement, and arrest the incessant metamorphosis of the internal surface of the organ, which has been going on for thirty years or more, and thus result in some lesion of this surface.

In closing, I will briefly refer to the plan of treatment which I adopt in this class of cases. Where the uterus is found to be increased in size and weight, I direct the patient to use, for a week previous to the return of the expected period, suppositories made after the following formula:

R. Extract of ergot (Squibb's) . . . ʒij
Cacao butter 3j

Divide into 12 suppositories.

One of these suppositories is to be introduced into the rectum, morning, noon, and night: and I always give positive directions that they shall be carried far up into the bowel, and the patient must keep the recumbent posture for at least one hour. These are to be continued for a week previous to menstruation, and also throughout its duration. I prefer to use ergot in this manner, rather than by the hypodermic syringe, for the reason that the remedy is easily handled by the patient or nurse, and you avoid the risk of troublesome abscesses in the tegumentary walls of the abdomen, which in my hands have frequently followed the use of the ergot by the hypodermic syringe.

If the hæmorrhage be prolonged, although not excessive, I infer that there is some lesion affecting the lining membrane of the uterus. I then have resorted to another plan of treatment, which, since I commenced it, I have rarely found necessary to repeat in any case beyond the second menstrual return. I introduce into the cavity of the uterus cylinders of iodoform, made according to the following formula:

R. Iodoform ʒijss
Gum tragacanth gr. xv
Mucilage [. q. s.

Divide into ten cylinders, each one and one-half inches in length. One of these cylinders is to be carried completely into the cavity of the uterus, and a pledget of cotton introduced against the cervix to retain it in position. Introduce one of these cylinders daily for five or six days previous to menstruation. The only objection to them, is the excessively disagreeable odour which attends their use. I have frequently heard patients complain of a most disgusting taste in the mouth, in less than two minutes after one of these cylinders had been introduced into the cavity of the uterus. But to me, the results which have followed their use have been most satisfactory. These cases of climacteric hæmorrhage are quite common, and are often found very troublesome to the practitioner. By the use of the suppositories of Squibb's aqueous extract of ergot, the chronic engorgement of the uterus may generally be effectually overcome. If the menorrhagia still persist, we have good reason for suspecting lesion of the internal surface of the uterus, which, I think, is cicatrised by the cylinders of iodoform. I have formerly used for this purpose sulphate of zinc, introduced into the cavity of the uterus, and in some

cases of profuse hæmorrhage the solution of the persulphate of iron; but, in all those cases in which the cylinders of iodoform have been used for some days previous to the appearance of the flow, there has been subsequently no hæmorrhage of sufficient importance to make the solution of the persulphate necessary.

I have sometimes found it necessary to use the suppositories at each recurring period for several months, as the tendency to engorgement of the uterus is very difficult to overcome at the period of the menopause.

MITCHELL ON NEUROTOMY.*

Dr. Weir Mitchell, impressed with the idea that nerves in man repair damages, and reproduce excised portions to a far greater extent than has been imagined possible, has collected one hundred and twenty cases of nerve sections and excisions for the relief of neuralgia or chorea. The immediate result was total relief in ninety-six cases. As, in eight of these ninety-six cases, pain returned within a period too short to have permitted of nerve-repair, Dr. Mitchell speculates that the cause of relief may sometimes lie in some alteration which the shock of an operation effects in the sensorium. In support of this theory, he cites a case in which pain in the median was removed by section of the musculo-spiral nerve, and alludes to well-known instances in which the extraction of a tooth has dissipated supra-orbital neuralgia. Twenty-five out of the ninety-six cases remained well at the end of a year, but in five of these a relapse occurred within two years; twenty-six cases experienced a return of neuralgia within periods varying from one month to eighteen. As to the rest of the cases, the reports are incomplete.

Viewing the cases in which nerve-section failed to give permanent relief in the light cast upon them by three carefully observed cases of which Dr. Mitchell gives the details, it seems no longer doubtful that the failure has been due to regeneration of the cut nerve. Repair of a nerve may take place in six months; in one case it took place in a few weeks. The test of repair is not the return of feeling in the isolated parts, for that may be re-established in some way not understood by terminal or current anastomoses, but the recovery of power over the palsied muscles. To ensure permanent relief in all nerve-divisions, as much as possible of the nerve should be taken away, and the distal end should be doubled back on itself and secured in that position, or buried in the body of an adjoining muscle.

CASE I.—In November, 1871, Dr. Sapolini cut down on the musculo-spiral nerve in Miss S.'s arm, and removed one inch of it. The section caused atrophy of the extensor muscles in the forearm, entire loss of power to extend the wrist and fingers, but only slight loss of sensation in the hand. Within six months of the section, there were enlargement of the wasted extensors and some return of power to the wrist and fingers. During 1873 and 1874, the whole of the function in the extensor group in the forearm returned, only extension could not be kept up as long as in the left limb. As pain returned in

the line of incision, in the radial region and back of the hand, accompanied by false phlegmon there, and as Miss S. became addicted to narcotics, a fresh incision was made in the line of Dr. Sapolini's former one, and the nerve, which was found perfectly re-united, was again cut, three inches of it being removed. The nerve was of normal appearance, except that two enlargements or buttons of neuro-fibrous tissue, one inch apart, marked the site of the two ends of the divided nerve. Of these, the upper was the larger. The result of the operation was the complete relief of pain. This case is believed to be the first in which a nerve once cut, has, after repair, been cut a second time, so as to remove the restored portion. Repair must have begun in a few months, as within six months there was available neural connection between the two nerve-ends, and partial repair of the wasted muscles. The most interesting point in the case, is the evidence which it affords that we know as yet little about the surface-distribution of nerves. Arloing and Tripier have shown that in dogs any single nerve left uncut will leave the whole paw more or less sensitive. In this case the median nerve had been cut, and the musculo-spiral, and there only remained for the supply of the hand the internal cutaneous, musculo-cutaneous, and ulnar. Feeling, which by all old rules ought to have been annihilated in some districts of the hand, was nowhere absent. There was only some slight loss of sensation extending over the whole of the right hand—not quite as marked, however, in the ulnar distribution as elsewhere.

CASE II.—In April, 1874, one inch of the digital branch of the ulnar nerve on the fourth finger of the left hand of Mrs. M.— was excised for the relief of intense and intractable pain that had lasted for about thirteen years. Temporary relief followed, but the pain was worse than ever in eighteen months. Another operation was performed in November, 1875, when the formerly divided nerve was found re-united, with a bulb on the proximal portion and the other extremity, closely incorporated with the scar of the former operation.

CASE III.—On December 5, 1874, two inches of the radial nerve on the back of the forearm were removed from a patient fifteen years old, on account of persistent pain in the back of the hand, with great redness and swelling. In six weeks, the pain and a few weeks later, tactile sensation returned. On October 20, the operation was repeated, and the nerve was found reunited, with distinct bulbs of reformation. The distance between the bulbs was one inch and a quarter. The central bulb was the larger, and the peripheral one was constricted in its centre and had a figure-of-8 appearance. At the second operation, three inches of the nerve were cut out, and the distal extremity was turned back, so as to form a loop. There was loss of sensibility over a small area on the dorsal aspect between the thumb and forefinger, and some dullness of sensibility for a short distance around this area and on to the first phalanx of the finger and thumb. In a couple of months the region of lost and lessened sensibility had become hyperæsthetic, or perhaps, more properly, hyperalgesic, and on January 20, 1875, there was in the whole region on which sensibility was at first abolished or dulled, feeling either to the needle or touch; all contact being felt as unpleasant tingling, and touch as pain and touch.

The microscopic examination of the portions of excised nerve, in these three cases by Dr. Bertolet,

* Neurotomy. By S. Weir Mitchell, M.D., of Philadelphia, with an Examination of the Regenerated Nerves, and Notes upon Neural Repair. By B. M. Bertolet, M.D., Pathologist to the Philadelphia Hospital. *The American Journal of the Medical Sciences*, April, 1876.

showed the central enlargement to consist entirely of doubled contoured fibres which interlaced and crossed one another in every direction. The primitive fibres were not arranged in regular nerve bundles, but were more or less widely separated by connective tissue, which was most abundant towards the outer margins where the perineurium was slightly hypertrophied. The nerve-fibres in these nodules differed in no respect from those of a healthy nerve-trunk except in their irregular interlacings, but the nuclei of the nerve-sheaths were at not a few points more numerous than usual. The peripheral enlargements presented the same histological features as the central ones, but the primitive nerve-fibres were oftener arranged in parallel rows. Sections of the intermediate nerve between the neuromatous swellings were indistinguishable from perfectly normal nerve. The similar growths found upon nerve-stumps after amputation differ from these neuromata, in the far greater predominance in them of proliferation of connective tissue. In these neuromata, the still evident traces of increase by segmentation in the nuclei of the neurilemma, leave little doubt that these nuclei are the principal factors in the reproduction of divided nerves.

Dr. Bertolet has watched the histological changes in the sciatic nerves of kittens which he has experimentally divided. He has seen: 1. Swelling, greyish red or yellowish in colour of the divided nerve ends, owing to thrombosis of nerve-vessels and saturation of the primitive fibres with serum; 2. Coagulation of myeline, which breaks up into concentrically laminated fragments, fat-globules and granular masses of detritus; 3. Distension of the primitive sheaths and disappearance of the axis-cylinder; 4. Extension of these changes for a short distance along the centrally attached nerve and throughout the peripheral nerve to its ultimate branches; 5. Proliferation of the nuclei of the neurilemma in the central swelling and throughout the peripheral end of the nerve; 6. Elongation of the increased nuclei into spindles and disappearance of the medullary substance; 7. Protrusion from these spindle-shaped nuclei of long filamentous protoplasmic processes, which unite with one another and widen into narrow bands; 8. Appearance round these single contoured fibres of a second sharply defined glittering contour, and blending of these fibres into continuous medullary-sheaths, and disappearance of a large proportion of the proliferated nuclei; 10. Filling out of the nerve-sheaths with medullary substance around the axis-cylinders.

ROGER ON PUNCTURE OF THE PERICARDIUM.

In a paper communicated to the Académie de Médecine by M. Henri Roger (*Bulletin de L'Académie*, no. 44, 1875) the author commences by dwelling upon the difficulties in the diagnosis of pericardial effusions, and he quotes in illustration two cases operated upon by Vigla and Trousseau, in one of which a thin-walled dilated heart was mistaken for an effusion into the pericardium; in the other case an hypertrophied heart surrounded by membrane floating in only a small quantity of serosity was found *post mortem*. M. Roger fully endorses the opinion of Trousseau as to the difficulty of feeling sure of the existence of great pericardial effusion even in the presence of most of the usual signs, and as to the

necessity therefore of caution in proceeding to operate. Besides the chief indication for paracentesis furnished by the quantity of the pericardial effusion, there are other indications, for or against, which depend upon the nature of the fluid and the causes of its effusion. Is the operation of paracentesis applicable to cases of active or acute hydropericardium? Such cases, M. Roger observes, scarcely supervene save in Bright's disease, either primary or secondary to scarlatina. The serum effused is very thin and readily absorbed, neither the heart nor pericardium being altered in texture. The danger to the patient in such cases does not so much proceed from the fluid in the pericardium, which is indeed rarely excessive, as from the associated dropsy of the lungs and pleura. Paracentesis, under such circumstances, is therefore not to be recommended.

It is more especially in the large effusions of pericarditis that the propriety of surgical interference comes under consideration. But it is necessary to discriminate between the effusion of acute and of chronic inflammation. When acute pericarditis terminates fatally, death is much less the result of the effusion than of the associated structural alteration of the heart from endocarditis and myocarditis, as well as from other complications, rheumatism, pleurisy, etc. Pericardial effusions differ from those of pleurisy, in the greater abundance of the false membranes which sheath the visceral and parietal layers of the pericardium with thick irregularly projecting surfaces, and form partial adhesions imprisoning the effused liquid, and opposing any further collection. Then the cavity of the pericardium becomes closed by complete adhesion; and the heart remaining big, or becoming hypertrophied, there results a complex lesion which gives rise to most of the physical signs and functional symptoms of great pericardial effusion. Hence, in this cardiac symphysis, we have still another cause of error of diagnosis, and of danger in operating.

In certain cases, however, effusion rapidly takes place, preventing the formation of adhesions; and the absorption of such inflammatory effusions is less easy than of dropsical accumulations. The primary and secondary consequences of such vast collections in the pericardium are, in the acute stage, the most grave disorders of the circulation and respiration, threatening speedy death. And even if the constitutional resistance permit the disease to become chronic, the fatal issue, although retarded, will not the less surely occur, secondary lesions becoming developed and giving rise to defective blood-changes and slow asphyxia.

Under these critical circumstances, if we be sure of the presence of extensive effusion and of the absence of pleuro-pulmonary complications, paracentesis ought to be attempted to relieve the compression of the heart and neighbouring organs. Even if the fluid be most successfully evacuated, however, one must remember that the peril, although postponed and lessened, is not altogether removed; pericardial adhesion and its later consequences almost necessarily ensuing. M. Roger gives a case to illustrate that, on the other hand, an effusion apparently of the gravest kind may, under treatment by counterirritants and diuretics, recover. Thus the position of the surgeon is in these cases of acute pericarditis, an embarrassing one; there is the doubt on the one hand whether a cure will not take place by the efforts of nature unaided,

and on the other hand he feels that the operation will avert a pressing danger.

Cases of simple chronic pericarditis attended with great effusion are rare. Most commonly they are tubercular, as shown by the *post mortem* observations of MM. Chairou, Baizeau, and Trouseau. Two out of three cases of infants in which M. Roger operated proved to be tubercular. The disposition to interfere by operation is much lessened in cases in which the effusion is evidently of tuberculous origin.

Unlike pleuritis, pericardial inflammation rarely, in the first instance, gives rise to purulent effusion, and such an effusion consequent upon pyæmia or allied conditions does not call for surgical interference.

In sanguineous effusions into the pericardium, hæmorrhagic pericarditis, and sero-hæmorrhagic effusions secondary to mediastinal cancer, all of rare occurrence, an operation is contraindicated.

Paracentesis of the pericardium is a far more delicate operation than puncture of the chest-cavity. The mammary artery coursing along four or five millimètres from the margin of the sternum, the diaphragm, the left lobe of the liver, sometimes much enlarged, the lung and pleura, and, finally and most importantly, the heart itself, have to be avoided by the surgeon. M. Roger quotes two cases, one of M. Baizeau's, and one of his own, in which the right ventricle was apparently punctured in operations designed for the relief of effusion into the pericardium, and 100 to 220 grammes of venous blood removed respectively. Both cases survived the operation. Another disagreeable occurrence which may happen even if the right place be chosen, is for the puncture to be followed by no escape of fluid. The pericardium being only in lax connection with the wall of the chest, and much thicker and harder than the pleura, readily recedes before the trocar. With the fine needle of the modern aspirator, however, this difficulty is less likely to happen. The puncture should always be made directly from before backwards with a slight subsequent inclination of the point of the needle downward, as advised by Dieulafoy, in order to avoid the ventricle during systole. The fifth intercostal space at a point intermediate between the sternum and the nipple, but rather nearer the latter, is the place to be, as a rule, chosen for puncture. But the heart's apex, instead of, as is usual in such cases, impinging against the fourth space or fifth rib, may be lowered by dilatation, or drawn downwards by an adhesion to the diaphragm, when a lower point must be chosen for the puncture. The region within which the surgeon must operate in order to respect all important organs being very limited, it is evident that the smaller the trocar the better the chance of terminating the operation happily; hence the capillary instruments are much preferable to the trocar, even of small calibre, employed until recent times for paracentesis of the pericardium.

In conclusion, M. Roger gives some discouraging statistics as regards the curative value of the operation. Of fourteen cases collected by him, he finds that in six death has followed so closely as to be attributable to, or at least hastened by, the operation; three cases have appeared to have succumbed to the disease in from six weeks to six months after the operation. In three cases an incomplete cure was effected, the patients dying subsequently of organic heart-disease or tuberculosis. One case 'recovered' but remained a valetudinarian. And in one case only was a 'true cure' effected. M. Roger concludes, therefore, that notwithstanding undoubted improve-

ments in the modern operation, it remains a dangerous and doubtful remedy to be hazarded in extreme cases.

R. DOUGLAS POWELL, M.D.

HARRIS ON THE TREATMENT OF INEBRIATES.

Dr. Robert P. Harris, who, as attending physician to the Franklin Reformatory Home at Philadelphia, has had more than five hundred confirmed drunkards under his professional care, gives the results of his experience in the medical and dietetic treatment of inebriates in a paper published in the April number of the *American Journal of the Medical Sciences*. He begins by stating that there is no danger to the inebriate in suddenly cutting off his customary stimulus, and that, of the two systems, the *sudden stoppage* is in all respects preferable to the *tapering off*. Of the patients who have passed under his observation, the majority have drunk whisky, some having taken as much as a gallon of this a day for a short period, and a few strong subjects as much as a quart a day for a year or more. The average daily allowance, however, of whisky, has been a pint and a half per man. The habit of whisky-drinking is only interrupted in such inebriates by disorder of the stomach amounting to absolute inability to retain fluids, or by exhausting diarrhœa, hæmorrhage from the rectum, or epileptic convulsions. When submitted to medical observation, they are weak, nervous, inclined to emesis, and considerably reduced in flesh. It is in these cases, in which appetite has been long impaired or lost, and in which vomiting has been early and excessive, that maniacal excitement is most likely to ensue. When with maniacal excitement there are an asthenic type and a scarcely perceptible pulse, coma and death are to be feared. In the management of cases in which there are failure of appetite and vomiting, much benefit accrues from the use of a few spoonfuls of iced milk and lime-water given every fifteen minutes for two hours. If this fail, then a mustard plaster should be applied over the abdomen; the next resort being to opium, or bromide of potassium in combination with bicarbonate of soda. As soon as the stomach will bear it, beef-tea or chicken-water should be given, and that should be followed by eggs, toast, and mutton-chops. Bromide of potassium, or still better bromide of sodium, which is fifty per cent. more soluble, and entirely free from pungency, is next to be employed as a sedative and soporific, especially where there is danger of *mania à potu*. It is not only a wonderful hypnotic, but relieves the irritability of the stomach, diminishing its hyperæmic condition, and in some subjects removing all craving for alcoholic stimulants. Where the salts of bromine fail as hypnotics, morphia may be added to them. Tannin or acetate of lead will arrest diarrhœa. The great object of treatment is to make an impression in the shortest possible time, so that food may be taken.

Two things are to be especially avoided in the treatment of inebriates—tobacco and water. The former conduces to mania, the latter distends the hyperæsthetic or inflamed stomach, and prevents food from being taken. Hyperæsthesia, marked by tenderness of the stomach on the introduction of food, sometimes continues for days.

Hæmorrhage from the bowels, which is almost invariably from the rectum, may be stopped by in-

jections of solutions of ten grains of persulphate of iron after each evacuation.

The convulsions of drunkards, which occur in about 15 per cent. of inebriates, are, Dr. Harris believes, reflex in character, springing from the state of the alimentary canal, and are best treated by elimination of alcohol and by the bromides.

The mania of drunkards, if not prevented, may, Dr. Harris asserts, be cured in from two to four days by bromide of potassium, sulphate of morphia, or chloral hydrate with substantial diet and beef-tea.

Secrecy in prescription is advocated, so that the patients may not take to the habitual use of the drugs employed. Many drunkards indulge largely in tincture of valerian, bromide of potassium, chloral, and Hoffmann's anodyne, and these are sometimes believed to be antidotes to whisky. Dr. Harris has ceased to use all medicinal tinctures, hop-tea, wormwood, capsicum, and highly seasoned soups in the treatment of inebriates. These, he says, keep alive a desire for drink. He discountenances also pepper, spices, and horseradish. With an American partiality for restraint, Dr. Harris recommends that, when there is much restlessness in *mania à potu*, the patient should be fastened with wrist and ankle straps, with a view to induce sleep.

Convalescent inebriates have marvellous appetites, and rapidly gain flesh. This circumstance, taken in connection with the fact that they lose weight whenever they resume their intemperate habits, is seemingly regarded by Dr. Harris as proof that alcohol is not a food. Renal disorders are common in inebriates, but are seldom serious or persistent, and yield readily to treatment.

J. CRICHTON BROWNE, M.D.

HARDY ON CIRCUMSCRIBED PACHYMENINGITIS AND MENIÈRE'S DISEASE.*

In a lecture delivered recently at the Necker Hospital, Paris, Professor Hardy made the following remarks. I wish to-day, gentlemen, to bring under your notice an individual who is affected with a most singular, but at the same time very interesting disease. Here, in a few words, is his history. Some months since he noticed in both ears, but more particularly in the left, very pronounced deafness, at the same time that he experienced some pain in the head, near the left ear, which was itself on different occasions the seat of a discharge. The patient, who was a baker, was nevertheless able to devote himself to his business, until about a month since, when after having suffered for some days from an increase of pain in the ear, he was suddenly seized with vertigo, following which he had a fall so violent as to cause a contusion with excoriation in the temporal region. This dizziness lasted some minutes; the patient is unable to speak precisely as to its duration. He then felt a slight giddiness, but he remembers perfectly how and where he fell. When he came to himself, he was in bed and sleeping. The next day the dizziness still remained, as well as the pains; and this state of things continuing for several days, the man decided to come into hospital.

We found at once in him all the symptoms of an affection of the ear; the external auditory meatus was the seat of a sero-purulent discharge. On a careful examination of the tympanum we found that the membrane was slightly altered, that it had not

its normal translucency, and that it presented well marked injection indicating the existence of inflammation, in fact of myringitis. The membrane at the same time appeared perfectly free from any perforation, but for some days the external ear was the seat of a discharge which assumed the form of scabs.

Synchronous with these signs of inflammation we observed the symptom which the man complained of before his admission, viz., pain in the left side of the head, occupying nearly all the posterior and superior part of the cranium, that is to say, the periauricular region; and at the same time a peculiar dullness, a drowsiness, portraying itself by a peculiar aspect of the face, which was just that of a man stupefied; the patient remained constantly in the sitting posture, scarcely listening and not appearing to comprehend what was said to him.

More than this, when he went to and fro it seemed to him that objects turned round; he experienced a feeling of vertigo, of whirling.

Under the influence of treatment, or merely by the progress of the disease, the state of this patient gradually improved. At the present time there is no discharge from the ear; he is always deaf, but his sufferings are much lessened, and the giddiness has disappeared. He even walks about, without that continual fear of falling which he formerly experienced. More than this, the stupefied aspect of the face is slightly diminished, and examination of the ear reveals nothing particular.

What, then, was this disease? With respect to diagnosis of the affection present in the ear, we say that evidently it offered signs of an external and an internal otitis. The buzzings, the deafness, prove this positively. But these lesions fail to explain the diverse phenomena which this patient presented, and everything tends to make us believe that in him we had an extension of the disease of the ear to the adjoining parts, to the brain. If the absence of paralysis and of involuntary movements permits us to conclude the integrity of the brain itself, on the other hand, the dullness of intelligence, the vertigo, the stupefied aspect of the patient, are so many signs of cerebral compression. And here the symptoms ought evidently to make us think of inflammation of the dura mater, of circumscribed pachymeningitis, an affection characterised, as you know, by a thickening of the serous membrane, and by a deposit of false membrane on its internal surface, lesions which soon cause compression of the brain, which shows itself by symptoms analogous to those which this patient presented.

Having its seat in the first place in the petrous bone in the condition of osteitis, the inflammation is propagated thence to the membrane which covers the bone, and there is here produced a phenomenon absolutely identical with that which is observed in individuals, subjects of Pott's disease, where one often sees with the displacement of the bone, pain, abscesses, and frequently phenomena of paralysis consequent on compression of the medulla. And it may be noted here that this compression is not produced by the bone, but that it is the result of the propagation of the inflammation to the dura mater which covers them; in a word, of a pachymeningitis which oftentimes accompanies true myelitis, thus explaining the phenomena of paralysis of the lower limbs which is seen in Pott's disease.

But this patient exhibits a special phenomenon which has been rarely observed. I speak of the loss

* *Paris Médical*, April 13, 1876.

of consciousness which, in my opinion, marked the commencement of the actual disease, the pachymeningitis.

In fact, in presence of the sudden vertigo with which this man was seized, ought we not to ask whether we have not in him a case of that singular special disease which is known by the name of *Menière's disease*? In answer to this question I must give you, in a few words, the history of this disease.

It was in 1863 that this disease was first pointed out by Itard, physician to the Deaf and Dumb Institution. He reported the case of a patient who was seized suddenly with vertigo, which came upon him like a shock. This fact passed unperceived when, in 1861, *Menière*, also physician to the Deaf and Dumb Institution, read before the Academy of Medicine a dozen cases of vertigo supervening in individuals afflicted with deafness, and characterised by manifest loss of consciousness, vertigo causing the fall of the patient.

Since *Menière's* work, other similar observations have been undertaken, especially by M. Charcot.

This disease presents peculiar phenomena to which I can easily call your attention. The first point which strikes us is, that the individuals who suffer from this disease are always the subjects of previous deafness, which dates back to a greater or less time, to some months or often longer. Besides this, before the special attack which characterises this disease manifests itself, the patients generally experience tinnitus and buzzings in the ears, sometimes cephalalgia. In some persons these phenomena undergo a certain amount of recrudescence before this attack; then supervenes the dominant phenomenon constituted by the vertigo, that is to say, a sensation of whirling. Not only does it appear to the patients that they themselves are turning round, but even the objects before their eyes seem to be carried away in a similar manner. With this sensation of turning there generally supervenes another phenomenon much more serious, a falling of the body, which is ordinarily forwards, sometimes backwards, or to the right or left. Suddenly these persons are seized with an irresistible impulse which throws them forwards, and makes them fall sometimes with great violence. There are various degrees of intensity of this phenomenon. Sometimes the patients experience only a sensation of falling; the fall does not actually occur. If they be lying down, the bed seems to them to turn over, sometimes from left to right or from right to left, sometimes from before backwards, or from behind forwards. At other times, on the contrary, there is a real fall, of a more or less violent character. Sometimes the individuals affected with this singular disease simply allow themselves to fall into a seat, into an arm-chair, or softly on to the ground; sometimes they fall with such violence that serious wounds result. One patient whom I saw had received in this manner a very large wound of the forehead; another, seen by M. Charcot, had sustained a fracture of the nasal bones.

At other times, instead of this sensation of whirling and the fall, it seems to the patients as if the earth opened and they were precipitated into a gulf.

Whichever may occur of these particular phenomena, there is frequently produced a loss of consciousness which most generally is of short duration. It does not come on instantaneously, but super-

venes little by little. The patients feel that they are losing consciousness. In fact, this phenomenon shows the peculiarity that, when they come to themselves again, they recollect perfectly the circumstances under which the attack occurred. There is none of that incontinence of urine or of fæces which characterises some attacks of loss of consciousness. More often than not, however, there is nothing of this sort. There is vertigo, and there is the fall, but the patient is able to give a perfect account of all that has happened. Or even if the loss of consciousness do occur, it is of very short duration, and even allows the patients to continue to do something while it exists. Besides this, other curious phenomena are observed; for instance, we see in some cases vomiting supervening after the attack. In the case of one patient under my care, every attack of vertigo was followed by a vomiting of a peculiar character, inasmuch as it was not preceded by nausea, and it was simply due to the action of the brain on the stomach. Finally, after these attacks there sometimes remain headaches, malaise, and especially buzzings in the ears, which last for some hours.

The attacks of loss of consciousness and of vertigo generally recur with more or less regularity. Some patients often have daily attacks, others every eight days; some, however, only have two or three attacks a year. In a word, the recurrence of the attacks is extremely variable. Nevertheless, this we can say, that there are generally many attacks, and that the disease lasts many months, sometimes even many years.

This is certain, that the disease may be cured, and that it causes during its continuance an increase of deafness, which, according to M. Charcot, may even become complete, and may remain in that state after the cure. However that may be, I have treated a patient, whom I have reason now to consider cured, since for ten years she has not had a single attack, in whom deafness, which depended on a very trifling obstruction of the ear, increased during the disease, and then returned after the cure to its former condition.

In these patients, in cases where a necropsy has been able to be made, alterations have been found in the semicircular canals of the labyrinth, these alterations consisting either in an effusion of blood pure or mixed with pus, or simply in a certain amount of redness in the membrane which lines these canals. Whatever it may be, it is evident that these lesions of the semicircular canals react upon the brain, and are the cause of the troubles from which individuals afflicted with *Menière's* disease suffer.

The relation which exists between these lesions of the internal ear and the symptoms I have mentioned, has been confirmed by experimental researches made on animals by certain physiologists. Flourens and Vulpian have shown that these lesions cause in animals phenomena of rotation and of propulsion forward, similar to those which are produced by destroying the peduncle of the cerebellum.

I conceive that in deaf people, in whom the internal or the auditory nerve is altered, the disease is propagated towards the semicircular canals, and that thence are manifested the attacks which we have just noticed. But even here, as in numerous cerebral affections, there is still something obscure, unknown in the pathological anatomy, and we are unable to give any reason for the intermittence of the attacks. I could cite many cases of *Menière's* disease to you, but

I will confine myself to the relation of the following.

I have under my care in the City a lady who, three years ago, while walking in her garden, during a storm, was suddenly seized with a falling of the body forwards. It seemed to her that there was before her a gulf into which she was precipitated. She did not lose consciousness; she remained a moment on the ground, and then raised herself up. The same accident had happened to her twice before, ten years previously. Following this attack she had similar ones, always recurring in the same manner. Once the propulsion forward was so violent that, as the result of the fall, she received a severe wound on the forehead. Under the influence of treatment or of the evolution of the malady, instead of an actual fall or stroke, this lady began to feel merely a sensation which she herself regarded as so slight that, if it happened when she was talking, the conversation was not interrupted. At the present time, buzzings in the ears returning at the menstrual periods, with heaviness in the head, are all that remain of the affection. In this lady, during the illness, the deafness with which she was affected increased considerably; but after the cure it returned to its former state. In her case the administration of bromide of potassium, in three grain doses, caused no amelioration; moreover, it gave rise to a rubeloid cutaneous eruption, which I have never seen one like before. I then took to having her bled once a week for a month, then every fortnight, then every six weeks, and lastly every six months. For two years, the attacks have not reappeared.

Some days since I was consulted by a patient who, about ten months before, was seized with vertigo, followed by a fall. Quite recently, while shaving, the same accident again happened, leaving him scarcely time to throw down his razor and fall into an easy chair. Two days later, while in bed, he experienced the same symptoms; it seemed to him that his bed turned over and he was about to fall. He never lost consciousness. The physicians whom he consulted diagnosed vertigo *a stomacho laeso*, and prescribed quassia, alkalies, and bitters. The attacks continuing, the patient came to me. Suspecting Menière's disease I questioned him, and he told me that for two years past he had heard only with one ear. I did not hesitate then to make my diagnosis; he suffered evidently from vertigo *ab aure laesa*, and not from vertigo *a stomacho laeso*. I bring the question back now to its point of departure, and ask if our patient has been suffering from this Menière's disease. I think not. We have only in support of this opinion the conditions of the fall; here, I think, the attack has simply marked the commencement of a pachymeningitis.

The prognosis of his affection is little serious; little by little the health of the patient will be re-established, and though for some time the buzzing in the ears will remain, he will be able to attend to his occupations. As to the treatment which we have followed, it has consisted in the administration of repeated purgatives, the application of cupping-glasses, and blisters to the nucha. Thanks to these measures, we have been able to obtain a very great amelioration of the symptoms.

W. DOUGLAS HEMMING.

PROFESSOR SCHIFF, the distinguished physiologist of Florence, has been appointed professor of physiology in the new medical department of the University of Geneva.

ANATOMY AND PHYSIOLOGY.

PERRETTI ON THE TOXICOLOGY OF CAFFEIN.—Binz observed some time ago that the temperature of the body was considerably increased after large doses of caffein. J. Perretti (*Dissertation*, Bonn, 1875, and *Centralblatt für die Medicinischen Wissenschaften*, no. 52, 1875), has made numerous experiments on dogs, cats, and rabbits, and found that there was an increase of temperature of 1.4° Cent. (2.52° Fahr.) after the subcutaneous injection of half a gramme of caffein in a dog weighing 2,700 grammes (about 6 lbs.) The effect does not last long, like all the other phenomena produced by the drug. During the increase the animal is in a state of general muscular tension, and it appears to the author highly probable that a direct excitation of the spinal cord and the increased innervation of the motor apparatus dependent thereon causes the great production of heat. The pulse is simultaneously much increased, the salivary glands secrete profusely, and the sensorium is obviously excited. The respiration is rapid, and is paralysed by fatal doses. That artificial respiration can avert death (Uspensky) is confirmed. Neither rigor mortis nor increase of temperature occur, even when the dose is so large that paralysis of the respiratory centre takes place. The spasms from poisoning with caffein do not, as a rule, appear in animals when artificial respiration is kept up, nor in curarised frogs, nor in extremities after division of the nerves, at least not in frogs. In poisoning with caffein, alcohol seems to be valuable. Three experiments show that quite another picture is presented when caffein and alcohol are given simultaneously. The temperature of the intoxicated animal rises again; the affection of the brain becomes less, and the inability for movement passes into violent effort to move. If the dose of the antidote be too strong, then it unites its effects with that of the alcohol.

TARCHANOFF ON THE INFLUENCE OF CURARA ON THE QUANTITY OF LYMPH, AND THE EMIGRATION OF THE COLOURLESS CORPUSCLES OF THE BLOOD.—J. Tarchanoff (*Archives de Physiologie*, November, 1875, p. 33) combats the assertion of Drozdoff that curara dissolves the colourless corpuscles of frogs. Of four sorts of curara which Tarchanoff added in a concentrated solution to the colourless corpuscles suspended in frog's serum, two produced after a long time a solution of the colourless corpuscles; several, however, showed that the free granules remained completely undissolved. Whether this phenomenon depends upon accidental impurities in the curara, the author leaves undecided; the two other portions of the poison were completely inactive.

If curara were injected subcutaneously into a frog, a pretty large dose being given, but not sufficient to paralyse the heart, the number of colourless corpuscles diminished and that of the coloured increased; the number of the former (from a series of experiments conducted after Malassez's method) contained in a cubic centimetre of blood fell to about half of the normal; the latter rose to double. After the return of mobility, *i.e.* after four or five days, the normal condition returned. As the cause of this condition of the blood is to be regarded a very great increase of lymph, very rich in colourless corpuscles, and which coagulated very rapidly, not only in the

dorsal lymph-sac, but also in other lymph-sacs of the body. Specially well filled was the sac underneath the tongue. [This pronounced filling of the lymph-sac was known to Bidder, who referred it to paralysis of the lymph-hearts.]

The author, in confirmation of several papers emanating from Ludwig's laboratory, assumes an increased transudation from the blood-vessels of curarised animals. A lively emigration of colourless elements was directly observed in the tongue and mesentery of curarised frogs. This also occurred when the cerebro-spinal axis was carefully destroyed without hæmorrhage. In both cases the author assumes as the cause of emigration an increased transudation and increased lateral pressure in the small arteries in consequence of the extinction of the tonus. As long as the paralysis continued, the blood became poorer in serum and white elements. With cessation of the paralysis the pronounced diminution stopped; the lymph-sac emptied itself again, and the normal condition of affairs was soon restored. This emptying could also be produced by electrical stimulation during the period of paralysis.

In conclusion, the author makes some objections to Cohnheim's doctrine of suppuration. The condition of curarised frogs proves that enormous outwandering of colourless corpuscles can take place, which is not to be identified with suppuration. In addition, the author has convinced himself, like Malassez, that with continued suppuration the number of white blood-corpuscles does not diminish, but rather increases. Further, Ranvier has lately observed the direct division of white blood-corpuscles.

Lastly, the author cites some results upon the distribution of curara in the tissue-juices and upon its excretion. For testing its presence, he employed the physiological method. The blood of large strong curarised frogs never showed, when it was injected into the lymph-sac of small frogs, poisonous properties. Only in very small animals it produced a slight muscular weakness which rapidly disappeared. The bile and lymph gave negative results; the urine on the contrary was very poisonous, and this took place from the beginning of the curarisation, and during the entire duration of the paralysis. If the cloaca were occluded, the urine stagnating in the bladder lost its poisonous properties. Under these circumstances, therefore, the curara is destroyed.

GRÜTZNER ON THE FORMATION AND EXCRETION OF PEPSIN.—P. Grützner describes some new investigations on the formation and excretion of pepsin (*Breslau*, 1875, 8vo, pp. 86, and *Centralblatt für die Medicin. Wissenschaften*, no. 52, 1875.)

I. On the estimation of pepsin.—The author gives more exact details regarding his colorimetric method. He recommends the filling of a series of equally thick test-glasses with solutions of carmine of different strength for comparison. Carmine is dissolved in ammonia and diluted with glycerine, until a 0.1 per cent. solution of carmine is obtained. Of this solution of carmine, 0.1 cubic centimètre is dissolved in 19.9 cubic centimètres of water, 0.2 in 19.8, etc., up to 1.0 cubic centimètre in 19 cubic centimètres of water. One can, of course, only regard the colour of the fluid by solution of the coloured fibrin as a measure for the quantity of pepsin, as long as some fibrin remains uncoloured. The differences of several fluids containing unequal quantities of pepsin become indistinct when the

action lasts for a very long time, as the weak solution of pepsin ultimately dissolves all the fibrin.

Then there follows a critical and experimental treatment of the question whether pepsin is used up during digestion. The experiments of the author were made thus. Relatively large quantities of hydrochloric acid and pepsin were treated with different quantities of fibrin. Large quantities of fibrin constantly required longer time for their solution than when the amount was small; at least, this is true of not too concentrated solutions of pepsin. In other experiments, the solutions of pepsin were allowed to act for varying periods of time on fibrin, and then the amount of the pepsin in the fluid was estimated by the colorimetric method. In such cases, the amount of pepsin was smaller the longer the action of the fibrin on the fluid had lasted. It therefore follows that *pepsin is used up during digestion*.

II. The quantity of pepsin in the stomach under different physiological conditions.—Schiff asserted that certain substances, e.g., dextrose, on being introduced into the stomach, or by direct introduction into the blood were able to increase extraordinarily the quantity of pepsin in the mucous membrane of the stomach, to load the gastric follicles with pepsin. These results had never been confirmed. The author ascribes the error in Schiff's results to this:—that Schiff, by his method of extracting the mucous membrane with small quantities of slightly acidulated water, obtained very varying quantities of pepsin in solution. The quantity of pepsin obtained under these conditions does not bear any relation to the quantity of pepsin actually contained in the mucous membrane; mucous membranes poor in pepsin appear to give up their pepsin easily. In addition, many substances when introduced into the blood possess the property of changing the mucous membrane of the stomach so that it gives up its pepsin more easily. The author shows that common salt possesses this property, and so does one of Schiff's peptogenic substances—viz., dextrose. By employing the method of Schiff one obtains results similar to his; still the conclusions he drew from his experiments were erroneous.

To determine the quantity of pepsin under different physiological conditions, the mucous membrane, with the muscular coat removed, was washed and dried on blotting-paper. On drying, the sub-mucous tissue for the most part adhered to the paper; the dried fragments were powdered and preserved in an exsiccator. This preparation was extracted with glycerine and then with 0.1 per cent. of hydrochloric acid. The glycerine extract represents the free pepsin, the acid one the fixed. For 0.1 gramme of the dried mucous membrane, 8 cubic centimètres of glycerine, and the same amount of hydrochloric acid were employed; extraction with glycerine lasted eight days, that with hydrochloric acid twenty hours. Of the extracts so obtained 0.1 cubic centimètre, or, when the pylorus had been used, 0.5 cubic centimètre was treated with 15 cubic centimètres of hydrochloric acid of 0.1 per cent. and fibrin. The microscopic investigation of the mucous membrane was conducted after hardening in alcohol, the sections being coloured with carmine, picrocarmine, or aniline blue. Stomachs of the dog, cat, pig, and rabbit were employed. The results obtained were the following.—1. The quantity of pepsin in the mucous membrane varies. 2. It varies with different conditions of the peptic cells; if these be bright and large, they contain much pepsin; if they be shrivelled and

turbid, little; a moderate size and turbidity correspond to a medium amount of pepsin. 3. What is true of the peptic cells of the fundus is also true of the same cells of the pylorus; large clear cells indicate a large amount of pepsin. 4. The turbidity of the peptic cells is a sign of the secretion of pepsin. With regard to the relation of the formation of pepsin to the food taken, the following are the results in the dog, the pylorus being employed. The quantity of pepsin increases from the time of taking food till about the ninth hour thereafter; it falls slowly till the thirtieth, and again rises slowly till the fortieth, and then remains so. The fundus after the introduction of food after long fasting, yields very rapidly a great quantity of pepsin till about the ninth hour. At this time the minimum quantity in the fundus corresponds with the maximum quantity in the pylorus. From this point onwards the quantity rises till the thirtieth hour after food, and remains so for fifteen to twenty hours. If the fasting last longer (sixty or seventy hours), a spontaneous secretion occurs, the quantity of pepsin in the fundus diminishes. The conditions are similar in the cat, only here the first period lasts eighteen instead of nine hours. Similar results occur in the pig; in the rabbit, on account of the stomach always remaining full, the stages of secretion are not so clearly pronounced.

III. *The secretion of pepsin observed in dogs with gastric fistula.*—In the fasting condition scarcely any secretion takes place in the stomach. A fluid of alkaline reaction is generally discharged from the fistula—viz., the saliva which has been swallowed; only exceptionally does this contain pepsin. If indigestible substances which powerfully stimulate the stomach, are introduced into it, a profuse secretion of a very active gastric juice takes place, which soon (at most one or two hours) becomes much less active; six or seven hours after the introduction the quantity of pepsin again rises. Similar results occur on introducing foods. The increase in the quantity of pepsin from the sixth to the seventh hour is due to activity of the parts near the pylorus. The conditions for secretion are altered, however, when foods are introduced into a stomach not quite empty, as under ordinary circumstances is generally the case. The quantities of pepsin secreted by a stomach twelve to fourteen hours after a good diet on the introduction of more food are much smaller than after a continued long fast. The quantity of pepsin in the gastric juice diminishes continually; an increase in its quantity is not to be observed at any time. In the case of a dog suffering from an intense catarrh of the stomach for several weeks, produced by introducing some pebbles into it, the secretion was continuous, and was not, or but slightly, affected by the taking of food. The juice secreted was turbid, sticky, not always of acid reaction, sometimes neutral and even alkaline; it always contained pepsin, but sometimes extremely little. The author therefore recommends that in cases of chronic catarrh of the stomach only small quantities of food should be given at once, and soon thereafter 30 to 40 cubic centimetres of a 0.04 per cent. of hydrochloric acid.

IV. *On the participation of chlorides in the secretion of pepsin.*—If a pylorus which has been washed be extracted with glycerine, one generally obtains a very weak extract. If the pylorus be treated with solution of common salt the extract is very much more active. The common salt breaks up a compound in which the pepsin in the pylorus is con-

tained. If the common salt has also this action in the organism, mucous membranes rich in pepsin must also be rich in common salt. In fact, a series of experiments showed that the quantity of common salt in the dried mucous membrane varied from 0.6 to 1.5 per cent., and the large amount coincided with enlarged and clear peptic cells which contained a large quantity of pepsin. If a large quantity (10 grammes) of common salt be injected into the veins of a fasting dog, the pepsin is excreted more rapidly, so that one hour after the beginning of the experiment the mucous membrane is always thinner than in the animal used for the control experiment. This observation agrees with that of Braun on the increase of the secretion after chloride of sodium.

WM. STIRLING, D.Sc., M.D.

EULENBERG AND LANDOIS ON THE THERMAL EFFECTS OF EXPERIMENTS UPON THE NERVOUS SYSTEM OF DOGS.—Professors Eulenberg and Landois, of Greifswald, have published (Virchow's *Archiv*, April, 1876) the results of numerous experiments on dogs, which seem to have been undertaken with great care, and in which the time elapsing in each stage, as well as the readings of the thermo-electric needle, are carefully given. The following are some of their results.

1. Irritation of the cervical sympathetic in its continuity caused immediately cooling of the corresponding ear (about 1° C.), which continued even after the irritation had ceased for a time—fifteen to twenty seconds—and was followed by a sudden elevation of temperature to more than its original level (about 2° C. in fifty seconds).

2. Cutting the sympathetic in the neck caused at first a passing reduction (0.1° to 0.2° C., in ten seconds), followed by a steady and rapid rise of temperature in the corresponding ear (6° C. in seventy-five seconds).

3. Irritating the peripheral end of the cut sympathetic produced exactly the same results as irritation of its continuity.

4. Section of the sciatic nerve caused immediately a slow but steady rise in the temperature of the corresponding foot, equal to 3° C. in 275 seconds.

5. Strong irritation of the peripheral cut-end caused, after a short latent stage (fifteen seconds), a steady cooling of the foot (about 1.8° C.), which reached its maximum some time (sixty seconds) after the irritation had ceased, and was followed by a very slow rise of temperature. In this stage the peripheral end was again strongly irritated, causing a cooling of the foot, preceded by a latent stage (thirty seconds), which reached a less degree than on the first occasion, being only about 1.1° C. After this the temperature rose, but stopped at 1.1° C. below the original figure. R. SAUNDBY, M.B.

PATHOLOGY.

GENZMER ON CHANGES IN THE SPINAL CORD AFTER AMPUTATION OF A LIMB.—Dr. A. Genzmer (Virchow's *Archiv*, vol. lxi. p. 265) found the following alterations in the spinal cord of a man who died of typhus, thirty years after amputation of the right thigh in its lower third. Examined from below upwards there was nothing unusual in the *conus medullaris*, and a want of symmetry was first observed at the commencement of the lumbar

swelling; this was most marked at the junction of the lower and middle thirds, became again considerable above the middle, and disappeared in the upper third. The parts above the lumbar enlargement were normal. The change on the right side consisted in diminution of the anterior cornua, accompanied by a remarkable decrease in the number of the ganglion-cells; the anterior roots also were thinner and less numerous than on the left side. There were no perceptible differences in the structure of the parts, neither were the nerve-tubes thinner, as described by Vulpian, nor were the ganglion-cells corrugated, pigmented, and deprived of their processes, as in J. Thompson Dickson's case; if those of the right side were sometimes smaller, they were not constantly so. The posterior cornua and columns were healthy; the central canal closed throughout.

LEBERT ON ANEURISM OF THE PULMONARY ARTERY AND RHEUMATIC INFLAMMATION OF ITS VALVES.—In the *Berliner Klin. Wochenschrift* for May 15, Dr. Lebert, of Vevey, reports the case of a woman, aged thirty-five years, who was admitted suffering from considerable oedema of the legs, ascites, dyspnoea, and cough. Physical examination yielded the following:—Præcordial dulness much extended to the right and left; the apex-beat beyond the nipple line in the fourth space; dulness over the upper part of the sternum, and the left first and second intercostal spaces; over this area pulsation, systolic and diastolic murmur, and double thrill; at the apex a systolic murmur not continuous with the above; in the second right intercostal space a diastolic murmur. Over the lungs generally were heard catarrhal rhonchi. Hepatic dulness reached from the fifth rib to the costal margin. The urine contained much albumen, blood, and casts. Respiration 28, pulse 96. The sphygmographic tracing showed a marked respiratory wave. The pulse gradually rose to 130; and with increasing dropsy, drowsiness, and collapse, she died twelve days after coming under observation.

She had been well till seven months previously, when she had rheumatic fever, with much dyspnoea. The pain subsided in three weeks, but swelling and dyspnoea continued until admission. *Post mortem*, there were found dilatation of the right ventricle, globular dilatation of the pulmonary artery, and endocarditis of its valves. Of these, two were much larger than the third: all presented numerous vegetations on the cardiac surface, and somewhat fewer on the arterial surface and free edge. On the corresponding points of the ventricle and artery were similar deposits. The left ventricle was also dilated, and there were slight evidences of endocarditis of both sets of valves. The spleen was large, the kidneys dense, the lungs throughout crepitant, but slightly oedematous; the arteries free from embola. The author regards the valvular disease as too recent to have been the origin of the pulmonary aneurism, but supposes that the pre-existing dilatation may have determined the unusual localisation of an endocarditis, accompanying rheumatic fever.

F. TAYLOR, M.D.

BEIGEL ON GIANT-CELLS.—Dr. Hermann Beigel, in a paper (*Virchow's Archiv*, April, 1876) on the pathology of cauliflower excrescences, directs attention to the almost universal part played in morbid anatomy by giant-cells. He quotes the observations

of Johannes Müller on their appearance in cancers and enchondromata; of Kölliker, in the bones of the normal skeleton; of Wagner, in the arterial coats; of Rustizky, in the re-absorption of callus; of Virchow, in the lymphatic glands, and in the omentum in tubercular peritonitis; of Paget, in marrow tumours; of Schuh, in epulis; of Groh and Lanceriaux, in other tumours; of Langhans and Klebs, in tubercle, and in the early stages of elephantiasis by the latter; of Brodowski, in the granulations of chronic ulcers; and of Alexander Jacobson, in the healthy granulating wounds of soft parts. He thinks these researches prove that these cells cannot be considered as peculiar to any normal or pathological tissue, and that it may be said that under favourable conditions any cell may degenerate into a giant-cell; and he believes these conditions are present wherever a more rapid development or degeneration of tissue, or both together, are present.

FUCHS ON TRAUMATIC KERATITIS.—A long paper on this subject, by Dr. E. Fuchs (*Virchow's Archiv*, April, 1876), contains the result of original researches by the author into the normal anatomy of the cornea and the results of destructive lesions of its surface. His conclusions are as follow. The cornea may be said to be made up of formative elements capable of being brought into two separate morphological categories, which for the cells separate them as dendriform and straight, and for the other elements find expression in the spheroidal and spear forms. A wound made in the cornea by the red hot point of a needle has for its immediate consequence the death of the proximately cauterised cells—forming the vacuole zone, as he calls it. The cells next these respond to the irritation by proliferation, and form the irritation zone, and at the same time commences the wandering of white blood-corpuscles into the cornea. These new elements group themselves round the irritation zone, but after the lapse of one day begin to disappear by wandering to the surface of the cornea. After the third day a thicker belt of cells is built up by corpuscles floating to the outer edge of the irritation zone, which after the seventh day becomes changed into a thick wreath of spikes; this he calls the secondary proliferation zone. This last formation removes by pressure the slough caused by the cautery, which till then has covered the vacuole and irritation zones. A slighter wound, such as scratching the cornea, causes at once changes in the form of the cornea-cells; this ends by the death of the cells, and the subsequent development of an inflammatory process similar to that described above.

R. SAUNDEY, M.B.

SOCOLOFF ON THE PATHOLOGY OF ACUTE SWELLING OF THE SPLEEN.—Dr. Socoloff, of St. Petersburg, gives (*Virchow's Archiv*, February, 1876) the results of his work on this subject at Professor von Recklinghausen's Institute. The question proposed for investigation was whether any of the lower organisms are present in the spleen in cases of septicæmia, and if so, what relation they bear to that swelling. Virchow, in 1857, in a case of diphtheritic endocarditis, found the splenic arteries plugged by granular masses, which resisted the usual reagents, and which could therefore be easily distinguished from mere detritus. Waldeyer also has published a case of intestinal mycosis, in which the splenic vessels, and also those of other organs, were plugged with fungus-elements, and their surrounding parts

infiltrated with blood. And Birch-Hirschfeld, by means of experiments, has corroborated the significance of micrococci in swelling of the spleen.

Dr. Socoloff's observations are partly pathological, partly experimental. The former are based on twelve cases of typhoid fever, ten of pyæmia after fractures, six of puerperal fever, three of acute peritonitis, and others of intestinal and pharyngeal diphtheria, phthisis, endocarditis, scarlatina, acute rheumatism, and croupous pneumonia. The spleen was always enlarged, but varied in size in different cases. Its increase was due to engorgement, to hyperplasia of its tissues, and enlargement of the cells of its pulp. The altered cells grouped themselves in clusters, and the adventitia of the blood-vessels was infiltrated with young cells. In one case the Malpighian corpuscles were enlarged, and notably in typhus and pyæmia, circumscribed capillary extravasations were present. Micrococci were only found in certain cases. Notes of six such are given. Two of pyæmia, one of phthisis, three of enteric fever.

The following conclusions are formed from these observations. 1. Swelling of the spleen in infective diseases is not always due to the presence of fungus in its tissue. 2. In all cases in which positive results were obtained, colonies of micrococci were seen both in the vessels and in the pulp-tissue. In the vessels they formed plugs. In their walls they were between the trabeculae of connective tissue. 3. When these bodies were present, the infection was of recent date.

The question, therefore, still remained unsolved whether, since their presence was not constant, micrococci were more than an accidental phenomenon, which had no causal relation with the splenic swelling. On the other hand, it is quite possible that they, having originated such a swelling, had lived their life and perished ere the swelling had subsided.

These points could only be settled by experiment. To this end a series of rabbits were taken, and putrid inflammatory and other fluids injected into the peritoneum.

The results appear to have been pretty constant, viz., a more or less intense peritonitis and swelling of the spleen in all cases, with, if the animal died within three or four days, micrococcus-masses, in the blood-vessels of the spleen and kidneys; if it lingered over a week, the absence of any such bodies, but the presence of an excess of pigment in the spleen.

From this it appears that, though swelling of the spleen is always associated with the presence of micrococci in its tissues in the early stages of infection, it is not so in the later periods, and cannot therefore be dependent entirely upon their presence.

The experiments were all conducted under nearly comparable conditions, both as regards the animals used and the fluid injected; and if after long periods of infection micrococci were not met with, while they were constant in all cases of early poisoning, it is clear that they must have disappeared previously.

This point having been determined, the different results obtained from the examination of the human spleen in the various infective diseases receives an explanation. It does not follow that because, in our anatomical inquiries, only a small number of the investigated cases showed the presence of micrococci, therefore they did not exist in the remainder. It is much more probable that their course in the human spleen will correspond exactly with that of those in the lower animals under experimentation,

and it has been seen that in these the micrococci disappear after a certain time. In typhoid fever they are only present in the early stage, *i.e.* when the changes are confined to the neighbourhood of the valve, and have not gone beyond swelling and superficial ulceration. Moreover, the observations both of Billroth and Socoloff, seem to show that certain multinucleated cells in the splenic pulp are only found in the early stage of the typhous process. These were found in the cases now recorded, and their presence further links the micrococci with the early fever. In the first described case of pyæmia, the individual whose spleen and other viscera were permeated by micrococci died very quickly.

The adoption of the hypothesis of the disappearance of the fungus from the tissues is by no means without precedent. Lukomsky has found a similar course of events in erysipelas, and Obermeier's observations on the spirilla of relapsing fever are well known.

It is important to add that Birch-Hirschfeld has found micrococci present in the blood seven or eight days after the injection of the poisonous material, and he also states that whenever the spleen is large micrococci are to be found in its tissues. Dr. Socoloff attributes such statements, differing as they do somewhat materially from his own, to the fact that the former was content to see only isolated grains, while he required evidence of the formation of colonies. Dr. Socoloff's results are also at variance with those of Birch-Hirschfeld, when he says that after the injection of putrid fluids into the serous cavities a local inflammation may result, and the animal die without the presence of any number of micrococci in the blood, and without any swelling of the spleen. On the contrary, the former has found, even one hour after the infection, that the lymphatics of the diaphragm and the blood-vessels of the spleen were filled with parasitic organisms.

The swelling of the spleen in these cases appears to be due partly to an inflammatory process which the micrococci, free or enclosed in wandering cells, or subsequently building colonies, excite; partly to the engorgement which necessarily follows the plugging of many of the vessels by these foreign particles.

MEDICINE.

BENEKE ON THE PATHOGENESIS OF ARTICULAR RHEUMATISM.—In the *Berliner Klin. Wochenschrift* for March 1876, are some remarks by Professor Beneke on the pathology and etiology of articular rheumatism based on 246 cases of the disease. Of these, however, 64 were either from the first cases of osteo-arthritis, or passed directly from the acute into a chronic stage, in which condition they first came

under notice. No cause whatever for the disease could be discovered in 32 cases; of the remaining 214, a directly hereditary or family tendency could be traced in 74, while in the other 140, sexual excesses, exhausting confinements and lactation, uterine diseases with the functional disturbance consequent upon them, over-exertion, chills, and less frequently rickets, chorea, epilepsy, meningitis (in early life), gonorrhœa, syphilis, measles, etc., preceded the development of the disease. The author regards these as so many conditions exercising upon the nervous system a depressing influence, which, acting upon a body in a certain state of preparation, leads to the production of rheumatism. This state of preparation consists in an increased formation and accumulation of organic acids, the result of the interference in the metamorphosis of muscular tissue which disturbed innervation brings about. Such a view is supported by the well known condition of the secretions in rheumatism, by the beneficial influence of alkaline vegetable juices, and by the extreme rarity of rheumatism in herbivorous animals. Only, then, in those in whom this humoral foundation is present will the above etiological conditions set up the disease; where it is wanting some other affection will be the result, and in healthy individuals probably none at all.

GOLTDAMMER ON SPINAL APOPLEXY.—In the January number of Virchow's *Archiv* (Bd. lxvi. p. 1) Dr. Goldammer describes fully a case of paraplegia, which he regards as undoubtedly the result of spontaneous hæmorrhage into the spinal cord, independent of any previous inflammatory softening. On April 21, 1874, a girl, aged fifteen, apparently in perfect health, was suddenly seized with violent pain in the back between the scapulae, extending rapidly to the arms, the lower part of the chest, and the epigastrium. The right leg became at once powerless, and in another half hour the left was in the same condition. Two hours after the commencement of the attack she had complete paraplegia, complete anæsthesia up to the level of the nipples, persistence of reflex movements in the lower extremities, and paralysis of the bladder; in the upper extremities, severe pains, but free movement and normal sensation. The functions of the brain were perfect. The case continued to present all the characters of paraplegia from a localised lesion of the spinal cord. The electric irritability of the muscles remained normal; the urine was retained; and bedsores appeared. After two months the reflex irritability became excessive; somewhat later spontaneous twitchings of the paralysed muscles took place; and towards the end of August the legs were persistently contracted, at first in the extended, later in the flexed position. Increasing bedsores led to a fatal result, twelve months from the beginning of the illness. On opening the spinal canal, the dura mater was found normal; the spinal cord was contracted to half its width at a point corresponding to the second dorsal nerves, and here the pia mater was a little thickened. This narrow portion had a vertical extent of about one-sixth of an inch. On section there was no trace of grey matter, but the greater part was of rather hard consistence, and in colour rusty brown with whitish yellow streaks. The white columns on the left side were softer and tinged grey. A rusty streak was traceable in the situation of the right posterior cornu upwards to the cervical swelling, and downwards as far as the fifth dorsal nerves. On micro-

scopical examination, the dense rust-coloured portion was found to consist of a firm network of connective tissue fibres, with embedded fat-globules, large masses of hæmatoidin crystals, and collections of brown granular pigment. Nerve-elements were entirely wanting, and the vessels showed fatty and granular degeneration. The greyish columns on the left side, and the whole cord for a few millimètres above and below the rusty cicatricial tissue, were in a condition of softening with the usual granule-corpuscles replacing the nerve-fibres and ganglion-cells. Secondary degeneration could be traced downwards in the lateral columns to the lumbar region, and upwards in the posterior columns as far as the calamus scriptorius.

F. TAYLOR, M.D.

DAVIS ON REVACCINATION DURING AN EPIDEMIC OF SMALL-POX.—Dr. William B. Davis, in a paper read before the Cincinnati Medical Society (*New York Medical Record*, March 25), comes to the following conclusions from observations in that city during an epidemic of small-pox. 1. Exposure to infection and intense epidemic influence largely increase the susceptibility of the system to the influence of vaccine virus and accounts for the unusual number of successful revaccinations during the existence of an epidemic. 2. Variola and varioloid give no more protection from a recurrence of variola than vaccination. 3. The cicatrix is not a safe criterion of the degree of protection given by the vaccination from which it resulted. 4. It is advisable to revaccinate upon every exposure to infection, unless it has been done recently with success. 5. Those who were successfully revaccinated were, to some extent, susceptible to the variolous influence, not that all would have taken the infection, for an epidemic never takes all the unprotected. That they are in some danger is proved by the results of vaccination in the hospitals and standing armies of Europe. In the Prussian army the annual death-rate from small-pox, before revaccination was introduced, averaged 104. During the twenty years immediately succeeding the establishment of systematic revaccination there were but forty fatal cases (an average of two per year), and Simon says but four of these had been successful revaccinations.

W. DOUGLAS HEMMING.

OPPLER ON A CASE OF MENINGITIS WITH APHASIA.—Staff Surgeon-Major Oppler, M.D., of Danzig, reports the following case in the *Deutsche Medicinische Wochenschrift* for April 15, 1876. Grenadier K., aged twenty-one, was admitted into the infirmary June 30, 1875. On admission, he seemed stupid. There was considerable difficulty in getting him to give his name, and his memory was so bad that it was difficult to believe that two days before he had been in perfect health, and discharged all his duties. But just two days before admission he was taken ill without any known cause; had had severe headache, but came into hospital because of several shivering fits, alternating with heats, and because he felt very ill. He was a strong, well-built man, and lay on his back, complaining, in broken words—which were uttered one at a time—of pains in his head, chest, and limbs. His manner was very apathetic. The bladder was much distended; but after a good deal of persuasion he passed a quantity of clear yellow urine free from albumen. His muscular weakness was great; the tongue moist, red, not coated, and not deviating

from the middle line. There were no physical signs of serious chest disease. Cardiac dulness was normal, and the heart's sounds clear. The abdomen was soft, concave, and not tender. There was no eruption, and no enlargement of either liver or spleen. The pupils acted well. Pulse 70, of moderate tension. Temperature 38°C . (100.4°Fahr). The bowels acted yesterday. There had been no vomiting yet. It was evident that speaking was very difficult to him. Single words were pronounced hesitatingly (*zögernd*). July 1. The patient had slept; he was still apathetic; to-day his facial expression was painful; the tongue was red, and quite dry. Pulse 80; temperature 38.5°C . ($=101.3^{\circ}\text{Fahr}$); respiration 25. There were a few moist râles in the chest, but elsewhere vesicular breathing; catarrhal sputum in moderate quantities, easily disposed of. The pupils still acted well, but his speech was worse than yesterday. He quite understood what was said to him, but could not properly and clearly finish the words he began—the words themselves were right, but his utterance of them was only partial; and when he noticed that he could not finish his sentence, he became unwilling to do so and angry, and screamed out inarticulate sounds instead of the word he wanted to finish. His appetite was slight. Towards evening he grew drowsy, but could be awakened by calling to him. Sensibility was diminished all over the body, and irritants produced but little effect. July 2. The patient was drowsy, yet could be easily awaked; he talked a little better, or, at all events, it was easier to understand the words which he still only half-pronounced. Every now and then the angles of the mouth were retracted, and he had painful yawning. In the evening his speech was again embarrassed. Instead of the word he wanted, only the first syllable, or sometimes only a single letter of the word, was screamed out, and he nodded with the head as if contented, when the words were properly finished for him. The pupils were still not small. The patient understood what was said to him, and pointed out the parts of his body where he felt pain. Pulse 60; temperature 38.4°C . ($=101.2^{\circ}\text{Fahr}$). July 3. He passed a tranquil night, and lay quiet, but slept little. During the night it was noticed that his speech became worse; he now seemed unable to speak at all. His facial expression was tranquil. Pulse 60; temperature about half a degree (Fahr) lower. He still showed that he understood, and made his wants known by signs, yet seemed unable to speak even a single syllable. The abdomen was retracted, like the inside of a boat in outline. All the right half of the body had perfectly lost sensation. On the left side it was very imperfect. Violent yawning was continuous; the pupils acted well. July 4. His state was the same as before. To-day the patient could only say 'Herr Jes...' and 'Ja wohl,' although hesitatingly. Morning temperature 38.4°C . ($=101.2^{\circ}\text{Fahr}$); evening 39.3°C . ($=102.8^{\circ}\text{Fahr}$); pulse 72.

There was on July 5 no change in his condition; to all questions he answered 'Herr Jes...' ('Lord Jes...'). Pulse 72; temperature 38.8°C . ($=102^{\circ}\text{Fahr}$). His urine was of a deep yellow, without sediment, and free from albumen. In the evening he tried hard to say something, but could not get out a word. July 6. He was very restless in the night. He did not now attempt to speak. His intellect seemed very much affected; he no longer put out his tongue when told to do so. Pulse 80; temperature 38°C . ($=100.4^{\circ}\text{Fahr}$). The left pupil seemed

a little smaller than the right; both acted well. Sensation was as before. In the evening he seemed quite unconscious. He made continual snatching movements with his right hand, and picked at the bed clothes. The pupils acted badly now. The temperature had risen nearly 1°Fahr ; pulse 70. July 7. He was perfectly unconscious; there were continuous snatching movements with both hands, so that his arms were never quiet. The right pupil still acted very slowly; the left was dilated and immobile. There was still sensation in the left half of the body. Pulse and temperature as last night. July 8. There was deep coma. The left arm, flexed at the elbow, could not be extended. The right pupil still acted; the left was as before. His respiration was deep and noisy, with deep sighs in between. In the evening the right pupil was very much contracted and immovable, the left large and fixed. Tracheal râles set in. Pulse small, and not to be counted. Temperature 38°C . ($=100.4^{\circ}\text{Fahr}$). He died early next day.

At the necropsy there was nothing remarkable in the skull, or in the (longitudinal) sinus. There were very numerous and remarkably large Pacchionian glands on the summit of both hemispheres. When the dura mater was removed, the vessels on both hemispheres of the brain were seen to be greatly congested; the pia mater was whitish-grey and opaque, especially in parts where the vessels branched, otherwise the convexity of the brain appeared normal. At the base the pia mater of the left side, in the hollow between the brain and the temporal lobes, was thickened, and so to speak, felt (*verpilzt*); and in the midst of this thickened and matted tissue there was a layer about an inch in its longest diameter, of greenish-yellow masses of oval form; the brain-substance above appeared perfectly normal to the naked eye, and free from any deposits or thickening. There was no exudation into the ventricles, and the pons and other great centres exhibited nothing abnormal. On both hemispheres, beneath the pia mater, many cysticerci, about the size of peas, were found between the gray and the white matter. The vessels of the spinal cord were much injected, and there was a good deal of cerebro-spinal fluid. The substance of the cord was pale, and somewhat denser than normal. Except hypostatic congestion of the lungs, and considerable swelling of the bronchial mucous membrane, the other organs of the body appeared quite healthy.

In commenting on this case, Dr. Oppler remarks how little fever accompanied these serious symptoms, and notes the absence of vomiting and constipation. There were no convulsions—the pupils acted well for a long time—there was no delirium. Consciousness was maintained till the sixth day of the attack. There were no symptoms of cerebral irritation.

Although there was some torpor the patient was easily roused, and though he had lost his speech, he made his wants known by signs. Till the day before death, his pulse was neither quickened abnormally, nor abnormally slow, varying between 60 and 80. It is also noteworthy, that on July 1, the second day of disease, a characteristic affection of speech enabled the lesion to be located in the left half of the brain. Most, if not all, of the cases of aphasia reported have been from destructive causes—tumours, apoplexy, softening, etc., none of which were present here. He had meningitis of the convexity in very slight degree, and more severe meningitis at the base of the brain, but limited to the fossa of Sylvius, on the

furrow between the anterior and posterior lobes, where only it had gone on to suppuration, but, as far as the naked eye could determine, the brain-substance was not affected; it would therefore seem as if all that is required for aphasia is inflammatory irritation in the fossa of Sylvius, or thereabouts, without the second or third convolutions being actually diseased. The intelligence displayed by this man negatives Trousseau's dictum that there must necessarily be some affection of the intellectual faculties in aphasia. The patient perfectly knew the words he wanted to say, but could not co-ordinate the muscular groups, whose combined action is necessary to speech of articulate kind. The opinion of Bouillaud and Trousseau, that the 'speech-centre' of the brain must be wholly or almost entirely destroyed in aphasia, is also upset by this case.

[It seems a pity that the man was not asked to write, as there does not seem to have been any hemiplegia; also that the brain-substance was not examined by the microscope. The case is, however, very carefully reported, and is extremely interesting. It fully confirms Dr. Hughlings Jackson's view, that the kind of injury is less important than its topography, and that suddenness, or initial force, is of more consequence than mere magnitude.—*Rep.*] W. B. WOODMAN.

FOURNIER ON SYPHILITIC PHTHISIS.—In the *Gazette Hebdomadaire de Médecine et de Chirurgie*, November and December, 1875, M. Fournier, the eminent syphilographer, publishes a most elaborate lecture on the pathology and clinical features of syphilitic phthisis. Syphilis can affect the lung in two distinct modes; first, directly producing specific lesions, as, for instance, gummata and the like; secondly, as a generally predisposing cause of phthisis, acting in the same way as insufficient food and bad air.

Syphilitic lesions of the lungs are rare, though not so rare as has been imagined, for they are generally overlooked during life, and only detected in *post mortem* examinations. They for the most part accompany tertiary syphilis, and generally syphilitic disease of some standing, but occasionally are the result of hereditary taint, and have been detected in the lungs of syphilitic foetus. M. Fournier only recognises two forms of syphilitic lesions; (1). Simple hyperplasia; (2). Gummata.

Simple hyperplasia closely resembles syphilitic hepatitis, and consists of cell-proliferation in the parenchyma, thickening of the septa, and consequent narrowing of the alveoli and degeneration of the contained epithelium through pressure. The new tissue constitutes at first the nucleus of interstitial pneumonia, but this is eventually transformed into hard fibrous masses. The bronchial tubes abutting on these masses become flattened and gradually obliterated, thus terminating in ampullæ. Two forms of this lesion exist, the circumscribed and the diffused. The pleura overlying these masses is prominent, white, and shining, when the hyperplasia is recent. When it is of old date, the lesion gives rise to a stellate depression on the lung-surface, resembling similar scars observed on the liver.

Gummata in the lung do not differ greatly from those in other organs. When fresh, they are solid tumours of nearly equal consistency, dry on section, varying in hue from a yellowish-white to a greyish-yellow, with a caseous centre of rounded or slightly irregular form, varying in size from a hemp-seed to a

walnut. They are few in number, and this alone distinguishes them from tubercles, for often only a single one is found; the whole number rarely exceeds six or eight. They are situated not in the pulmonary membrane itself, but separated from it by an intermediate zone of grey fibrous tissue, constituting not a true cyst but a kind of enveloping shell. Gummata generally affect only one lung, and the surface rather than the deeper lying portions, also the lower lobe in preference to the upper. They disintegrate by fatty metamorphosis in the centre, extending to the circumference; and at the same time inflammatory ulcerative changes take place in the neighbouring structures; causing perforation of the bronchi, and thus affording a means of exit for the contents of the gumma. In this way a cavity is formed, the walls of which are often covered with a white caseous material, the residue of the eliminated gumma. Externally the cavity is sheathed by a hard condensed grey fibroid tissue, the shell of the gumma. Sometimes, through rarely, by the union of several of these an anfractuous cavity may form. If death does not intervene, the tendency is towards recovery, and the walls of the cavity commence to approximate, contraction gradually taking place, proofs of which may be seen in the stellate cicatrices sometimes noticeable in the parenchyma of the lung. It is not uncommon to find in connection with gummata the first form of lesion, namely, simple hyperplasia.

M. Fournier draws five points of anatomical distinction between syphilitic gumma and tubercle.

1. *From situation.* Tubercle usually attacks (in process of time) both lungs, and as a rule the upper lobes. Gummata are limited to one lung, and may be situated in any portion of it.

2. *Number.* Gummata are few and as a rule solitary. Tubercle sooner or later becomes confluent.

3. *Size.* Gummata are larger than tubercles, and never miliary in form.

4. *Colour.* Gummata are always white or yellow, and never semitransparent like miliary tubercle.

5. *Consistency.* Until softening takes place, the gumma is of more equal consistence than tubercle, and when it softens it does not break down so completely on account of its fibrous shell. Microscopically, no absolute distinguishing features exist between tubercle and gumma.

The formation of syphilitic lesions in the lung takes place not only insidiously, but in a manner so latent, even to the patient, that, even when they have attained a certain degree of development, the symptoms are obscure. They consist of slight discomfort in respiration, slight cough, often dry, and if expectoration exists, it is scanty, and of a catarrhal kind. The physical signs are negative, unless the gumma be superficially situated, and then it may give rise, over a circumscribed patch, to diminished clearness of stroke-sound, and to weak breathing, with prolonged expiration. Later on, the symptoms and signs become more marked; the dyspnoea increases, but never passes a mean intensity; the cough becomes more severe and spasmodic; expectoration is abundant, yellow, mucopurulent, and even purulent; and very frequently hæmoptysis takes place. M. Fournier denies the statement of some writers, that hæmoptysis is less common in syphilitic than in ordinary phthisis, but he admits that the amount expectorated is generally less. After this, the changes in the general condition closely resemble those of ordinary phthisis. Symptoms of weakness increase, and are

accompanied by loss of colour, flesh, appetite, by languor and dyspepsia, later on by hectic, night-sweats, progressive emaciation, and physical signs denoting extensive excavation, and finally by death, in the same manner as in chronic consumption.

The course of syphilitic phthisis is usually a slow one, and far less rapid than that of tuberculosis, except when other organs become involved, when the course becomes rapid.

M. Fournier distinguishes three varieties of the disease. In the first it is *latent*, when the pulmonary lesions are of so circumscribed and localised a character as to cause neither dyspnoea nor disturbance to the general health, and therefore are not suspected during life, but detected after death.

The second variety is where lesions suffice to cause some distress of breathing, but not to produce change in the general condition, which remains excellent. The patient thrives and fattens, but complains of slight cough, expectoration, and dyspnoea; and the physical signs indicate a limited induration or excavation.

The third variety combines severe local and general symptoms, and the physical signs present all the features of advanced ordinary consumption.

The prognosis of syphilitic phthisis depends on the extent of the lesions and the influence of treatment. Putting aside the latter, M. Fournier states that it is possible for lesions, which remain localised, and affect the general health only to a slight degree, to undergo spontaneous cure, proofs of which are often furnished by *post mortem* examinations.

Where syphilitic phthisis is a general affection, and especially if other viscera besides the lungs are involved, the natural tendency is towards a fatal termination. The diagnosis of syphilitic phthisis is very difficult. In addition to the peculiarities given above, may be mentioned a remarkable tolerance by the system of the lesions, even when extensive, the patient retaining his flesh and strength to a considerable degree. When this is the case, syphilis should be suspected, and a remarkable illustrative instance is quoted from M. Gubler's practice. Another point of diagnosis is the rate of evolution, which in syphilitic phthisis is very slow, whereas in tubercle it is rapid. M. Fournier admits that this tolerance of the system is seen also in scrofulous phthisis, and therefore cannot be depended on for diagnosis; but he advocates in all doubtful cases the application of specific treatment, which will soon settle the question.

This treatment consists of iodide of potassium, from two to four, five, and even six grammes daily, and small quantities of mercury introduced by friction through the skin, as the method least likely to disturb the digestive and nutritive powers. *Locally*, M. Fournier recommends flying blisters, cupping glasses, and painting with tincture of iodine, and *generally* cod-liver oil, bark, iron, mineral waters, and hydrotherapy.

The results of treatment depend on the extent to which the general constitution and powers of nutrition of the patient have become involved. If they be extensively injured, treatment comes too late. If, on the other hand, the lesion be recent, and only betrayed by functional disturbances, the prospect of a complete cure is most hopeful. The first signs of improvement are lessening of cough, expectoration, and of distress of breathing, which symptoms often disappear entirely. Cavities contract and no signs remain of what appeared to be very extensive lesions.

M. Fournier ends with four axioms of great importance.

1. Tertiary syphilis can produce in the lungs lesions, which either locally, or by reacting on the general health, simulate pulmonary phthisis.

2. These pulmonary lesions of syphilis are often amenable to specific treatment. However grave and important they may appear, they are far from being always beyond the resources of art.

3. Consequently, when a case of pulmonary lesion presents itself, it is important, unless the existence of tuberculosis be quite certain, to ascertain if the lesion can be traced to syphilis. It is necessary always to bear in mind that syphilis is a possible cause of pulmonary lesions.

4. When syphilis can be suspected to be the cause, the primary indication is to prescribe specific treatment, which in similar cases has been sometimes followed by the happiest results.

C. THEODORE WILLIAMS, M.D.

GOETZ ON A CASE OF CHOREA TREATED WITH BROMIDE OF POTASSIUM.—The case described (*Medicinisches-Chirurgisches Centralblatt*, March 24, 1876) is the first of a series of three, in which the author recently witnessed the good effect of the drug. It occurred in a girl, aged eleven, whose only previous disease was scabies. She is described as intelligent and industrious, though somewhat hasty and easily irritated. The family history was remarkably good. The mother attributed the onset of the disease to the following incident. One evening, about a week before Christmas, 1874, the girl was busy in the kitchen, when the noise of a pigeon in the chimney so startled her that she rushed out of the room to her parents. About eight days after this, involuntary movements of the hands and feet were first noticed, and from that time steadily increased. At the first visit the nature of the affection was quite evident. When told to walk alone, she raised one foot, stretched it out, and instantly drew it back again. She threw her arms about, moved her body to and fro, wrinkled her forehead, blinked, stared, made grimaces, and every now and then sighed deeply. This 'disturbance of co-ordination' affected nearly all the voluntary muscles; speech was somewhat inarticulate, the tongue was extruded obliquely and with difficulty; but deglutition was unimpaired. The girl appeared well developed for her age, somewhat pale, but without other indications of anæmia. At the heart's apex was a scarcely audible blowing sound, which some days later disappeared; and temperature and pulse were normal. On the supposition that the symptoms might be due to worms, calomel, with *santonin*, was ordered, but without result. Then, as the anæmia had become more pronounced, iron was resorted to; but with no better effect. On the contrary, the contractions became more and more violent, deglutition so difficult that she had to be fed artificially, and speech finally ceased altogether.

After this, she was not seen for eight days. At the end of that time her condition was appalling. She was sometimes thrown up in the air out of bed. On trying to stand upright, she fell in a heap, curled up on the ground like a worm; she was quite as unable to sit up, and could not even raise her head. The mouth was wide open, the lips cracked, the face and conjunctivæ reddened, respiration difficult, feeding attended with great difficulty, and speech completely lost. She was feverish, and had become

thinner. The heart-sounds were normal; the pulse accelerated, temperature 101.8° Fahr., the skin was hyperæsthetic; there was no photophobia. During sleep all the symptoms ceased.

Bromide of potassium was now given, beginning with 15 grains *per diem*; the quantity was increased daily by 15 grains, until the maximum, 75 grains, was reached. The beneficial influence of the drug was soon apparent; within eight days the contractions diminished, the fever disappeared, the temperature and pulse became normal, the mouth less open, respiration quieter, and sleep was easily obtained. The treatment with 75 grains was continued. At the end of another eight days, improvement had steadily gone on, so that she tried to say a few words, which, however, were scarcely intelligible; she could also sit up in bed for a short time. In fourteen days more the symptoms had ceased altogether; convalescence was rapid, and the girl has since been quite strong and healthy.

RALPH W. LEFTWICH, M.D.

RAYMOND ON TUBERCULAR MENINGITIS OF THE MOTOR CENTRES OF THE ARM.—At a recent meeting of the Société de Biologie de Paris, reported in *Le Progrès Médical* of April 22, M. F. Raymond pointed out that since the study of cerebral localisations had entered upon a genuine clinical phase, thanks to the analytic method propounded by M. Charcot, a certain number of very important facts have been adduced in favour of the doctrine. He had lately had an opportunity of observing with M. Gubler, of Beaujon, a patient whose history was particularly interesting in this relation. This patient, a man twenty-two years of age, was admitted into the hospital in the early part of the month of January last, and then presented obvious symptoms of pulmonary tuberculosis, not however very pronounced. The affection, indeed, seemed to be progressing slowly. He was thin, pale, coughed a good deal, and was a little feverish.

On January 28 he began to complain of violent pain in the right hypochondrium, and two days later vomiting came on. This recurred frequently, the ejected matter having a greenish colour. At the same time he suffered from severe headache, which affected chiefly the left side of the head. Fever then showed itself, the temperature rising to 140° ; the pulmonary lesions developed more rapidly, and the general condition became much worse. On March 24 he complained of great pain in his right arm, which seemed to him to be very heavy; at times he had great difficulty in moving it. On March 25 there were fresh pains in the arm, and motor paralysis was complete, sensibility being retained. In the evening, with a great effort, he succeeded in raising his arm to his head. The paralysis of the arm, up to the time of his death, presented the character of intermittence. There never existed any trace of paralysis in the right leg nor in the left arm or leg. Perhaps there was a slight degree of loss of power in the buccolabial muscle of the right side, and a slight deviation of the tongue to the left, but these symptoms were a little doubtful. In the whole case, there was nothing else comparable with the paralysis of the arm, which was indisputable. The patient died on April 4.

At the necropsy, far advanced tubercular lesions were revealed in the right lung, and the membranes of the brain were found to be the seat of tubercular granulations. These were found in the pia mater

over the right lobe, and there they were disseminated along the parietal branch of the Sylvian fissure. On the left side, in addition to the tubercular granulations there existed some meningitis with purulent deposits. The meningitis was, if it may be so said, circumscribed and localised on two convolutions, the anterior and posterior marginal near the paracentral lobe. There the tubercular granulations were very numerous, and formed a sort of tumour. The pia mater covered with pus, adhered closely to the subjacent cerebral tissue. In other parts, where there were granulations, there was no vestige of meningitis. No other cerebral lesions, foci of softening, or obliteration of capillaries, could be discovered. There was a small amount of fluid in the ventricles, but nothing to note in the spinal cord or nerves of the arm.

Such are the facts of this case, which may be summed up as follows: motor paralysis of the right arm, somewhat intermittent in the sense that it was at times complete, and at other times less absolute; and to explain this paralysis no other lesion than the tubercular meningitis in the region of the motor centres of the arm. J. CRICHTON BROWNE, M.D.

RAYMOND ON AFFECTIONS OF THE JOINTS AND BONES IN LOCOMOTOR ATAXY.—M. Raymond publishes in the *Gazette Médicale de Paris* (Feb. 19) two cases of this kind. In the first, a woman, aged fifty-two, who had been ill for many years, the necropsy showed atrophy of the prominent processes of the humerus, femur, tibia and scapula, without osteophytes, accompanied with fibrous degeneration of the muscles of the affected joints and softening and confusion of their ligaments.

The second case, also a woman, long under M. Charcot's care, beside a similar affection of the hip-joints, suffered from repeated fractures of the bones, which broke on slight movement in bed, and healed again with profuse formation of callus.

ABNORMAL INCREASE OF TEMPERATURE.—According to the *New York Medical Journal* for February, a patient who has been under treatment in the Mount Sinai Hospital has exhibited an elevation of temperature which is seldom noticed. The history is as follows. A German woman, aged twenty, was attacked seven months ago with convulsions. She was under treatment by an irregular practitioner before entering the hospital. The treatment consisted in freely bleeding the patient from the arm at short intervals. When she came under observation at the hospital, it was supposed that the convulsions were of an hysterical character, and for this purpose the strong induced current was applied. Some time afterwards she noticed an hyperthesia of the hand, which extended upward, and by degrees involved the arm, shoulder, and side. The temperature was then taken in the rectum, and found to be 110° Fahr. This high temperature lasted only for a very few hours, and then subsided to 99° and 100° . At first it was supposed that the apparent high temperature was due to some imperfection of the thermometer, but with different instruments the same result was obtained. It has been found that the marked increase of temperature occurs with an attack of pain. The diagnosis that has been made, is of meningitis affecting the basilar portion of the brain or upper part of the medulla oblongata.

WALCHER ON CEREBRAL SYMPTOMS DURING THE OPERATION OF INJECTING THE PLEURA

WITH CARBOLIC ACID.—M. Walcher has recently related, in a paper read before the Medical Society of Strasburg, published in the *Gazette Médicale de Strasbourg* (quoted in *L'Union Médicale*, March 28), the case of a man, aged forty, who was afflicted with pleurisy, with considerable effusion on the left side, displacing the heart to the right. Paracentesis was performed; but, twenty days later, the effusion having reaccumulated, M. Walcher made an incision and inserted a drainage-tube, with a view to injecting carbolic water containing a little iodine tincture. All went well at first, until one day, perceiving that the liquid injected returned between the tube and the edges of the wound, a greater amount of force was used with the syringe, when suddenly the patient sank back, became rigid, with the head thrown strongly back, the features turgid, livid, and contracted, with trismus and contracted pupils, and whilst in this tetanic condition the respiration and pulse were arrested. In the course of an hour the patient, without having regained consciousness, fell into a comatose slumber. He remained drowsy and unconscious until the next day, when reason returned, but he had no memory of what had passed. The only symptom remaining was paralysis, with numbness and almost complete insensibility of the left arm to above the shoulder. Ten days later a fresh injection into the pleura of alcoholised water, made, however, with more caution and more gently, led to a recurrence of identical symptoms, save that the paralysis affected the right side. The patient finally recovered, and resumed his usual work as a field labourer. M. M. Raynaud has explained similar epileptiform seizures (*Union Médicale*, 1875, nos. 137-140) as of reflex production, the pressure of the fluid upon the diaphragm affecting the phrenic nerve, and the influence thus conveyed to the medulla being reflected, not through the pneumogastric, but upon the vaso-motor nerves, causing contraction of the cerebral vessels; hence anæmia of the medulla, syncope, epileptic convulsions, coma, etc. M. Walcher does not accept this explanation. He regards the effect upon the brain as direct, not reflex, and as due to capillary embolism. He conceives that little sanguineous or fibrinous plugs produced in the pulmonary veins near the surface of the inflamed and suppurating pleura become detached by the force of the injection, and are conveyed into the left ventricle, and thence to the brain.

GUENEAU DE MUSSY ON THE TRANSMISSION OF SOUNDS THROUGH ENDOPLEURITIC FLUIDS OF DIFFERENT KINDS.—Dr. Gueneau de Mussy introduces a series of papers on the physical signs of pleurisy, contributed to the *Union Médicale*, January 4 and February 17, by a critical reference to the views of Dr. Bacelli, published in the *Archivio di Medicina*, Roma, 1875, respecting the value of vocal resonance in the diagnosis of empyema. Dr. Bacelli maintains that the usual circumstances from which the diagnosis of empyema is inferred—viz. the duration of the effusion, the œdema of the side, the altered state of nutrition, and the presence of intermitting fever and of progressive anæmia—are insufficient for the purpose, and he asserts that, contrary to the opinion of Trousseau, the most violent and prolonged fever may accompany effusions which are not purulent. The variable transmission of respiratory and vocal vibrations, according to the nature of the effusion, furnish, according to Bacelli, 'the absolute criterion for differential diagnosis.'

The vocal resonance to which Dr. Bacelli specially refers is distinct from ægophony. He gives it the name of *pectoriloquie aphonique*. In order to ascertain whether this sign be present, and with what degree of intensity, the observer should apply the unaided ear to the affected side, and direct the patient to whisper some rough word, such as *trente-trois*. 'The medium most appropriate for the transmission of vibrations is the thinnest and most homogeneous liquid. The more the fluid effused approximates in character to serum, the more easily the vibrations, even the lightest, will be transmitted. It suffices, then, for the observation, to make the patient articulate in a whisper a single word whilst one auscultates the chest, and the more the liquid effused departs from the constitution of serum the thicker it is, and the less its homogeneity, from the presence of amorphous protein-bodies and morphological or corpuscular elements, the less will be the completeness and extension of the transmission of even the strongest vibration, such as that produced by the articulation of a word aloud.' This assertion, which is not in accord with the opinion of most authors, is supported by the observation of sixty cases, in all of which the diagnosis was verified either by *post mortem* inspection or by paracentesis. Dr. Gueneau de Mussy criticises one observation upon which Dr. Bacelli lays some stress as supporting his theory, viz. a case in which, from the perfection with which the whispering voice was conducted throughout the affected side, he judged the effusion to be quite limpid. On paracentesis it was found, on the contrary, to be yellow, opaque, and viscid, having the appearance of pus. On further examination by the microscope, however, this opacity was found to be due not to pus-cells, but to the presence of innumerable fatty granules, which entirely cleared up on the addition of ether. Dr. Gueneau de Mussy considers this fluid to have been originally purulent, but to have undergone fatty degeneration. He thinks that this rather adds to the value of Dr. Bacelli's observation, inasmuch as the *pectoriloquie aphonique* may thus bear witness to a molecular change in the fluid which may influence the prognosis and treatment of such a case.

The conduction of sound through fluid media increases with their densities. The intensity with which sounds are transmitted varies, however, inversely with the density of the fluid media. Still these facts, Dr. Bacelli observes, although so far in accordance with his observations, are not sufficient to account for the phenomena witnessed, for the density of pus is only very slightly greater than that of serum, and yet a sound which would be readily transmitted through a much thicker medium than pus is by it extinguished. Dr. Bacelli, in explanation of this difficulty, considers that the waves of sound passing through a heterogeneous medium, such as purulent fluid containing corpuscular elements, become by refraction, interference, and dispersion lost, just as rays of light would be under similar conditions. Dr. Gueneau de Mussy is not satisfied with this explanation, and thinks further experiments are needed to ascertain by auscultation the relative powers of transmitting sounds of water, serum, thoracic effusions, ovarian cystic fluids, etc.

Dr. Gueneau de Mussy proceeds to consider the mechanism of some of the physical signs of pleurisy. He points out that in certain cases of effusion into the pleura the affected side may yield considerable resonance, amounting to tympanic sound on per-

cussion; and he quotes a case in which such a sound succeeded to dullness, in spite of the stethoscopic signs still pointing to the presence of fluid. He considers this resonance to be due to a diminished tension of the thoracic wall, causing it to be more vibratile. The accuracy of this view was, Dr. Gueneau de Mussy considers, borne out by the fact that on making the patient take a deep inspiration and retain his breath, the percussion note again became dull over the base of the affected side, although resonant at the apex.

In M. Gueneau de Mussy's able and interesting paper, other points of interest are discussed respecting the physical signs of pleurisy.

SURGERY.

VAN BRABANDT ON A NEW METHOD OF SEARCHING FOR CALCULUS IN THE BLADDER.—Being obliged to make several punctures of the bladder, by Dieulafoy's apparatus, in the case of an old man afflicted with retention of urine, and suspecting from the symptoms the existence of a calculus in the bladder, M. Van Brabandt (*Annales de la Société de Médecine de Gand*, quoted in *Paris Médical*, March 30, 1876) made a very careful exploration of the cavity of that viscus by means of the cannula of the capillary trocar which he had inserted in the hypogastric region. We have here, says he, a very convenient method, and one which, I think, has not hitherto been employed by any surgeon. It should be of use in cases where the sound, introduced by the urethra, leaves the operator uncertain as to the presence of a calculus in the bladder. No point of the *bas fond* can escape the investigations of the cannula. In doubtful cases, urethral catheterism might be employed conjointly with exploration of the bladder by means of a stylet or cannula introduced by the hypogastrium. We are sure that, by combining these two diagnostic methods, one quite as harmless as the other, no vesical calculus could escape the search of the surgeon.

TILLAUX ON TORSION OF ARTERIES.—The following are the conclusions arrived at by M. Tillaux in a paper recently read before the Société de Chirurgie, on torsion of arteries (*Paris Médical*, March 30, 1876). 1. Torsion is applicable to arteries of all calibres, especially to large arteries. 2. A single forceps is necessary for this operation, whatever be the size of the artery. 3. The arteries must be seized obliquely by the forceps, and not in their continuity, so as to get between the jaws of the forceps the three coats in all their extent. 4. Twisting must be

continued to complete detachment of the part seized by the forceps. 5. The folding of the coats towards the heart advised by Amussat and English surgeons is useless. 6. Torsion is applicable to atheromatous or inflamed arteries. It is a precious means of obtaining hæmostasis at the bottom of wounds. 7. It favours immediate union of wounds by the absence of any foreign body. 8. As well as the ligature, it forms a safeguard against primary hæmorrhages. 9. Better than the ligature, it prevents secondary hæmorrhages. Since 1871, M. Tillaux has exclusively employed torsion after small and great operations. He has never had primary or secondary hæmorrhage in about a hundred great operations in which he has practised it.

KUHN ON A NEW METHOD OF REDUCING DISLOCATIONS OF THE SHOULDER.—In the *Gazette Médicale de Paris* (quoted in the *Paris Médical*, March 9, 1876) Dr. Kuhn, of Elbeuf, describes a new method of reducing dislocations of the shoulder. He says it is impossible to ignore the difficulties which often attend the reduction of dislocations of the shoulder. These difficulties are partly owing to the fact that the scapula follows the traction made on the humerus, which causes a loss of a large part of the force employed for the stretching of the muscles.

By adopting the reverse method, that is to say, by applying the force to the scapula whilst the humerus is the fixed point, we no longer reduce the humerus; on the contrary, we fix it and reduce the scapula. There is no loss of power, as it is easy to prevent the arm from following the scapula. The difficulty which is found in reducing these dislocations, however, arises not only from the mobility of the scapula, but also from the power of the muscles, which it is necessary to put on the stretch. It is easy to see that, by this new method of operating, we shall not have to overcome the resistance of the pectoralis major and latissimus dorsi, but of the scapulo-humeral muscles (subscapularis, supraspinatus and infraspinatus, and teres major and minor), which are much smaller and less powerful than the former.

Since the discovery of anæsthetics, we can overcome the resistance of muscles, by chloroform and ether, the administration of which ought to be pushed until relaxation of muscles is produced. Many practitioners, however, are opposed to the use of these sometimes dangerous means for an operation generally so little serious as the reduction of a simple dislocation of the shoulder.

By following out these principles it is possible, more often than not, even alone and without assistance, to reduce a dislocation of this nature. A cushion of a conical shape is to be placed in the axilla, the base of the cone being downwards; the surgeon, standing at the patient's side, lightly draws the arm downwards, and at the same time presses it firmly against the pad in the axilla, so as to make it into a lever of the first kind. Then, taking the inferior angle of the scapula in the other hand, he raises that bone and gives it a see-saw motion. Coaptation soon follows, the two parts returning to their natural position, by a simultaneous effort made on the lower extremity of the humerus and the inferior angle of the scapula. If the head of the humerus be displaced, forwards, the angle of the scapula should be directed outwards, at the same time that it is raised. It should be directed inwards if the dislocation be backwards. If any difficulty be experienced in making

the reduction, the task of holding and directing the arm should be confided to an assistant.

W. DOUGLAS HEMMING.

NUSSEBAUM ON THE TREATMENT OF CENTRAL LESIONS BY NERVE-STRETCHING.—In 1872, Professor von Nussbaum published his first case in which nerve-lesions, such as tonic spasm and pain, in a limb, due to peripheral irritation, had been treated successfully by exposing the main trunks of the irritated nerves and stretching these with considerable force. In the following case, reported in the *Aerztliches Intelligenz-Blatt*, no. 8, 1876, the nervous irritation was due to a central and not to a peripheral lesion. The patient, a Polish gentleman, aged thirty-five years, had for eleven years suffered from paraplegia, consequent on a fall in which the sacral region was much injured. During this period, there had been partial loss of sensation and total absence of voluntary movements. The bladder and rectum had remained paralysed, and there had been a continuous dribbling of urine. When the patient applied to Professor von Nussbaum, the skin over both buttocks and over both sides of the pelvis was marked by large depressed cicatrices from former bed-sores. The patient during the whole period of his illness had been much tormented by almost constant tonic spasms of both lower limbs, through which the knees had often been dragged up to the front of the chest. Chloroform having been administered, the following operations were performed with careful attention to all the details of the antiseptic method. A curved incision was first made in the right groin over and along the course of Poupert's ligament. The fascia having been carefully divided, the anterior crural nerve was exposed and separated from the vein and artery. The operator's finger was then hooked under the nerve so as to elevate it with such force that the right foot was moved. The nerve was then seized between the finger and thumb, and pulled downwards until it appeared to have been elongated. The inguinal wound having been carefully dressed, a longitudinal incision was made on the same side midway between the tuber ischii and the great trochanter, so as to expose the sciatic nerve, which was also elevated from its bed and pulled forcibly upwards and downwards. These operations were followed by immediate cessation of the spasmodic movements of the right limb. The wounds having healed rapidly, similar operations were performed at the end of a fortnight on the left side, where both the anterior crural and the sciatic nerves were exposed and stretched. The relief afforded by this treatment is stated to have been complete and permanent; and the patient, who for many years past had been always kept to his bed was subsequently able to get up and to move about on crutches, the paralysed limbs being furnished with mechanical support.

SCHAEFFER ON LITHIASIS PREPUTII.—Dr. Max Schaeffer of Bremen reports (*Deutsche Medicinische Wochenschrift*, no. 11, 1876), a case of this rare complication of congenital phimosis. When the preputial orifice is very small, smegma, epithelial scales, and urinary deposits, collected in large quantities about the corona glandis, may become dry and form hard concretions, the so-called preputial calculi, which give rise to excoriation and ulceration of the mucous membrane of the glans and of the inner surface of the foreskin, and ultimately to profuse and persistent suppuration. In some exceptional in-

stances these calculi may accumulate to such an extent as to surround the glans, to impair micturition, and to form a large tumour at the extremity of the penis. Dr. Schaeffer's patient was a peasant of the age of forty-six years, who had had difficulty in passing his urine since childhood, and had noticed for several years the gradual growth of a tumour over the glans. Dr. Schaeffer, on examining the penis of this man, found at its extremity a hard tumour of the size of a small apple, and covered by tense and glossy integument. When this swelling was compressed and moved from side to side, a noise was heard as of closely applied small stones being rubbed together. The preputial orifice could not be readily found, as the tense skin was studded with numerous orifices having intensely inflamed and excoriated margins; and when the orifice had been found, even a very small probe could not be passed through it for more than one centimetre of its extent. On firm digital compression of the tumour, urine could be forced out in drops from all the fistulous openings. The patient complained very much of the difficulty he experienced in passing urine, the process occupying each time about a quarter of an hour and being attended with much pain. The case having been diagnosed as one of congenital phimosis and consecutive preputial calculi, a long incision was made from behind forwards through the upper part of the distended prepuce. Forty calculi varying much in size were then removed, together with a quantity of calcareous powder. The calculi taken collectively weighed eleven grammes, and the largest calculi weighed one gramme. The surfaces of most of these calculi were marked by smooth facettes. Each calculus consisted of a nucleus of uric acid and a cortical portion of phosphatic deposits. The cluster of calculi had been before removal traversed by strong fibrous bands, which were the remains of the ulcerated inner layer of the prepuce. The glans penis had undergone atrophy through long-continued pressure; its mucous membrane was quite sound, and presented no signs either of recent or of old ulceration. The urethral orifice was very small. After the removal of the calculi, Roser's operation for phimosis was performed. The constriction at the extremity of the urethra was subsequently treated with complete success by continuous dilatation with an elastic catheter. The patient made a speedy and good recovery.

VOLKMANN ON THE OPERATIVE TREATMENT OF PREPATELLAR HYGROMA.—In the third number of the *Berliner Klinische Wochenschrift* of this year, will be found a contribution from Professor Volkmann, giving the results of this surgeon's experiences of the treatment of hydrocele by simple incision under antiseptic conditions and with subsequent antiseptic dressings. In no. 8 of the same journal, Dr. Volkmann describes the invariably good results obtained by a similar treatment of enlarged prepatellar bursa. Exposure of this sac by incision the author states, has hitherto almost always been followed by severe local reaction, analogous in its intensity and its reaction to the attack which usually results from slitting-up of the tunica vaginalis in cases of hydrocele. There is intense inflammatory action followed by profuse suppuration, and the healing process is very tardy. According to Heinecke, recovery after this operation is not to be expected until the end of five or six weeks. Cicatrisation is often interfered with by parabursal suppuration and

phlegmon about the knee, which render necessary repeated incision. These unfavourable results are most frequently observed after the single incision. Heinecke holds that partial extirpation of the affected bursal sac is a less hazardous operation; but this latter proceeding cannot be performed without reluctance, and so the attempts that are usually made to remove the swelling consist either in injection of tincture of iodine or in forcible compression. Volkmann reports six cases, which show that, where the sac-wall is not thickened or sclerosed, an enlarged bursa patellæ may be readily and safely treated by incision, when the wound is made under the carbolic acid spray and afterwards carefully dressed according to Mr. Lister's instructions. In not a single case did any suppuration follow the operation, nor did any phlegmon or inflammatory action appear on the soft parts about the knee. After the incision and removal of the fluid, the sac is injected with a weak solution of carbolic acid, and then occluded by firm pressure. During the after-treatment, the whole limb is kept at rest on a long splint. After a period of from eight to ten days, during which the wound has been dressed three or four times, the healing process is usually so far advanced that the only application required is a simple stimulating lotion, and in the course of the third week the patient may, in most instances, be regarded as cured. In cases of acute suppurative bursitis, rapid plastic occlusion of the sac may be effected by similar treatment, and the more readily when the patient has applied for treatment at an early stage, and before perforation of the wall of the sac and the development of parabursal phlegmon. Under the last-mentioned conditions, a favourable result of such treatment may often be attained, and not only the suppurating bursa, but also all its suppurating pouches may, according to Dr. Volkmann, undergo plastic occlusion after slitting up, injection with carbolic acid in solution, and drainage.

W. JOHNSON SMITH.

CZERNY ON THYROTOMY.—Professor Czerny (*Wiener Medizinische Wochenschrift*, February 26, March 4), publishes a very interesting case of thyrotomy. He commences by observing that the difficulty in selecting a particular mode of treatment becomes more difficult as the number of methods increases. Till 1860, tumours could only be removed by Desault's plan of thyrotomy, whilst now the endolaryngeal methods of laryngoscopists, subhyoid laryngotomy, and extirpation of the larynx, are practised. He states that 'he has nothing to say against the limitation, by Dr. Mackenzie, of the operation to those cases where an experienced laryngoscopist declares the removal by the mouth impossible, and he would not think of effecting extirpation by a wound in the neck until he had made persevering efforts to remove the growth by the mouth.' Although Dr. Czerny has several times removed growths in difficult cases *per vias naturales*, he admits that in one instance, in which he had recommended subhyoid laryngotomy, Scheck subsequently removed the new formation through the mouth by means of a galvanocaustic snare. Dr. Czerny would have been inconsolable at such a result had not a laryngoscopist, whom all the world acknowledges as an authority, also recommended the operation by the neck. Dr. Czerny thinks that this case tends to show that we are not at present in a position to draw statistical conclusions as to the most suitable operation, any

more than we can determine the duration of treatment, result to breathing and voice, and chance of recurrence, from the different surgical processes. The author considers that Dr. Trendelenburg's plan of plugging the trachea has rendered it safe to produce more complete narcosis in operating, and has thus tended to reduce the mortality, already small, and to diminish the chance of recurrence by permitting more complete removal. The author also believes that the disposition to recurrence is greatly reduced by washing out the larynx with a strong solution of perchloride of iron (30 per cent.) after it has been laid open.

If the statistics of published cases of thyrotomy be compared with those treated by endolaryngeal methods, a great number of children will be found in the first category, and very few in the second. Out of 239 cases whose ages are given by Mackenzie as treated by endolaryngeal methods, only eight (3·3 per cent.) were under ten years, whilst of forty-three patients thyrotomised fourteen (33·1 per cent.) were under ten years of age. The facts appear to prove that one set of cases are suitable for thyrotomy and another for the endolaryngeal method. The case which called forth Dr. Czerny's remarks was a boy seven years old, brought under the professor's notice on September 12, 1874. The patient had suffered for two years from hoarseness and dyspnoea, attributed to the pressure of a fibro-cystic bronchocele. Puncture and emptying the cyst caused no diminution of the dyspnoea; but after great difficulty a laryngoscopic examination was made, and the entrance of the larynx was seen to be blocked up with greyish-red granulations. Under treatment based on the supposition that the disease might be hereditary syphilis, the child improved remarkably in every respect, and on October 18, the right tonsil, which was greatly hypertrophied, was removed. A more complete view of the larynx was afterwards obtained, and the whole circumference of its orifice, from the sides of the epiglottis along the ary-epiglottic folds to the posterior commissure, was seen to be covered with vegetations. As the little patient often suffered from attacks of suffocation and was generally cyanotic, Dr. Czerny performed tracheotomy on December 7. Bronchitis supervened on the 22nd, but the boy ultimately made a good recovery and returned home. In May, 1875, the thyroid cyst was cured by an injection of iodine, and the most persevering efforts to remove the growth by endolaryngeal methods having failed, thyrotomy was performed August 2, 1875. Owing to the small amount of space at command it was found impossible to use the only specimen of Trendelenburg's tampon-cannula at hand, and the passage of blood down the trachea was prevented by previously tying soft sponge round the ordinary tracheal cannula. Chloroform was administered by the cannula, and the larynx was opened in the usual way. The whole cavity of the larynx above and below the vocal cords was seen to be covered with vegetations, which were removed with forceps and scissors. The raw surface was then swabbed with perchloride of iron, and subsequently the larynx was washed with carbolised water (2 per cent.). No sutures were used either to the cartilage or to the external wound, which was merely brought together with strapping. The wound healed in fourteen days without any fever or suppuration. In September the cannula was removed, as the breathing was good through the larynx. The laryngeal hyperæmia was treated by local application of tannate of glycerine, and afterwards with solution of nitrate of

silver. On October 20, the boy was discharged, speaking in 'a loud, but deep and rough voice.' On December 4, the patient was seen again; his breathing was perfect and his voice loud, though rough and uncertain. With the mirror the vocal cords were seen to be red, but perfectly mobile; the right cord was smooth, but there was a swelling of the size of a split pea covering the posterior third of the left cord. The author considers that the danger of the recurrence of diffuse papilloma is in a great measure removed, but should the small tumour grow, the boy would probably be sensible enough to permit endolaryngeal treatment; otherwise Dr. Czerny would not hesitate to repeat the operation as has often been done before. The extirpated papilloma consisted of a richly ramified areolar tissue, at some parts abounding in nuclei, at others more resembling a mytoma. [Dr. Czerny is to be congratulated on his successful management of this troublesome case. The presence of the bronchocele caused a complication in diagnosis and considerable difficulty in treatment, which was overcome by great skill and perseverance. It is to be feared, however, from the report of the present condition, that a recurrence will take place. Rep.] MORELL MACKENZIE, M.D.

VOLTOLINI ON FRACTURE OF THE BASE OF THE CRANIUM.—Number 1 of the *Monatsschrift für Ohrenheilkunde* for 1876 contains a review, by Voltolini, of cases of cranial fracture, recorded in England by Birkett, Heath, Morris, and Lucas. He thinks that in most of those cases in which what is called cerebro-spinal fluid exudes, and especially in those cases which recover, the fluid does not come from the subarachnoidean space, but from the fractured labyrinth. If, he says, the fluid be cerebro-spinal, there must be a rupture of the dura mater, of itself a dangerous injury, and the tear must gape widely to admit of exudation passing out for any considerable time; and that the latter can occur without any important inflammatory meningeal symptoms, as occurred in the first three cases, he cannot believe. Supposing a rupture in the dura mater, there are two ways by which the cerebro-spinal fluid may make its way into the external meatus; viz. either through the roof of the tympanic cavity into that cavity, and then through the membrana tympani; or the fissure goes through the petrous bone, in which case, if the dura mater and arachnoid be also torn, the fluid of the labyrinth and the cerebro-spinal fluid will both exude. The rapidity with which the lymph of the labyrinth can be renewed is unknown, so that it cannot be determined whence a large amount of fluid comes which flows from the ear. He thinks that the cases of Birkett, Heath, and Morris, which recovered rapidly, were cases of fractured labyrinth; and to prove that the labyrinth may be the seat of important disease without serious implication of the brain, he cites the cases of necrosis of the labyrinth and otitis labyrinthica, in which the whole disease is *extra cavitatem cranii*. He considers it desirable that in such cases a careful note of the acoustic power should be made.

On Mr. Lucas's case, Voltolini makes the following remarks. 'Death came here, as it can come by injuries to the heart. I once shot a deer with small shot, at about eighty or ninety paces. It ran in full swing about 2,000 paces, and then fell dead. On examining it, the only wound I could find was in the heart, into the substance of which a single small shot had entered, and thence bleeding into the peri-

cardium had ensued, which gradually becoming filled, brought the heart to a standstill, and death suddenly followed. It was even so in Mr. Lucas's case, through the pressure on the brain by the increasing bleeding between the dura mater and bone.'

W. LAIDLAW PURVES.

LEVIS ON THE PREVENTION OF PAIN AFTER APPLICATION OF THE ACTUAL CAUTERY.—Dr. R. J. Levis, Surgeon to the Pennsylvania Hospital, writes in the *Philadelphia Medical Times* for March 15, that, though the local anæsthetic action of carbolic acid has been for some time recognised by surgeons, no important practical applications appear to have been deduced, and its great powers in that direction seem not to have generally impressed the profession. He has been in the habit of taking advantage of this remarkable property of carbolic acid in his frequent resort to the actual cautery, with the result of the most complete avoidance of consequent suffering. His practice is to apply pure carbolic acid on and for a short distance around each point of application of the cautery, before the patient recovers from the influence of the general anæsthetic which has been used. For convenience of application, the crystals of carbolic acid are deliquesced by warmth, and the liquid applied with a brush. The part is then covered with any light dressing. Should pain recur after extensive or deep use of the cautery, the application may be renewed; but he has not, in his experience, found such resort necessary. Since the fact of the local anæsthetic action of carbolic acid has been familiar to him, he has more frequently used the actual cautery in surgical practice than formerly, particularly in neuralgic suffering and in chronic painful affections of joints, and always with freedom from suffering and with satisfactory results.

BESSEY ON THE REMOVAL OF A LYMPHOMA FROM THE RIGHT SIDE OF THE NECK.—Dr. William E. Bessey, in a paper read before the Medico-Chirurgical Society of Montreal (*Canada Medical Record*, March), describes the following case. This tumour had existed for a period of about sixteen years, gradually increasing in size, and at times becoming considerably swollen, and causing pain in the head, ringing in the ear, and aching in the arm of that side, with a feeling of tightness about the throat. It occupied the superior portion of the right posterior triangular space, and projected into the superior carotid triangle, lying upon the sterno-mastoid, and covering the chain of lymphatic glands along the posterior border of this muscle (it was made up of three of these glands hypertrophied), and was covered in by the fibres of the platysma myoides spread out to an aponeurosis. Its long axis was in a line with the fibres of the sterno-mastoid, and was crossed above by the posterior auricular, and a superficial cervical branch. The external jugular vein lay in immediate contact with it underneath, being in a sort of niche on its under surface, its fundus dipping down well into the superior carotid triangle. Its length was about six inches, its breadth about four inches, and it was very movable. The patient was a stout-built florid Frenchman, about forty years of age. Having chloroformed the patient, Dr. Bessey made a free incision along the posterior aspect of the body, and, getting at it from behind, enucleated it slowly. The adhesions to the surrounding structure were very extensive, and the small blood-vessels feeding it numerous. No vessel

sufficiently large to require ligatures was met with. By proceeding cautiously, examining each mass of adhesions before severing, and working with the fingers, he succeeded in loosening it, step by step, from the neighbouring glands, the subjacent muscle, the external jugular vein over which it lay in direct contact, and finally succeeded in removing it from its adhesions in the superior carotid space without any injury or accident occurring to any important part or blood-vessel in the neighbourhood. Thirty minutes were occupied in its removal, without any untoward circumstance occurring to complicate the operation.

The parts having been approximated, simple water-dressings completed the treatment, and an excellent recovery followed in a fortnight, with, however, some slight numbness in the right hand and arm. The growth, on examination by Dr. Osler, was found to be an adenoid tumour of the cervical lymphatic glands.

BUCK ON THE MIGRATION OF PURULENT MATTER.—In a paper read before the New York Academy of Medicine, and published in the *Richmond and Louisville Medical Journal* for March, 1876, Dr. Gordon Buck makes the following remarks on the conditions on which the migration of purulent matter depends, as regards the parietes of the lower abdominal and pelvic cavities. If we carefully consider the distribution of the peritoneum where it lines the parietes of the lower abdominal and pelvic cavities, we find it in the lumbar region covering the anterior surface of the psoas magnus muscle, and thence spreading out inferiorly and laterally over the iliac fossa, and further down over the walls of the pelvic cavity. In all these regions, as well as in the contiguous hypogastric and inguinal regions, this membrane adheres loosely to the surfaces which it covers, by means of a delicate connective tissue interspersed scantily with a fine adipose tissue, and can readily be detached by pressure with the ends of the fingers alone without the aid of a scalpel. The slight resistance to its spreading which supuration would encounter on this anatomical plane favours the migration of pus to a distant point, especially if aided by gravitation. This anatomical peculiarity also serves as a protection to the peritoneal cavity itself against ulcerative perforation of the membrane. On this same plane, migrating pus would gain access to the track by which the great sciatic nerve and vessels pass out through the ischiatic notch into the gluteal region. A further illustration of this subject is furnished in the case of what is known as psoas abscess, where supuration takes place in the lumbar or dorsal region of the spine, and depends on caries of the vertebrae. Aided by gravitation the pus follows the psoas muscle, and in its descent may take either one of two directions.

1. By pressing behind the iliac fascia, it may accumulate in the iliac fossa and make its way behind the outer half of Poupart's ligament, distending and elevating it in some degree, and then may arrive upon the upper part of the thigh, below the outer half of Poupart's ligament, where it presents a more or less extensive, elastic and fluctuating swelling. Continuing along the course of the iliacus and psoas muscles, the matter may burrow its way on even to the region of the hip joint.

2. Purulent matter in its descent from the lumbar region, instead of passing behind the iliac fascia, may keep in front of and between it and the peri-

toneum, and accompany the femoral vessels in their passage from the pelvis, behind the inner half of Poupart's ligament. In this case, a superficial sub-fascial swelling may form on the anterior aspect of the thigh, below the inner half of Poupart's ligament. Another point at which matter may make its escape from the pelvic cavity is in company with the obturator vessels as they traverse the obturator foramen, at its upper margin where the obturator membrane is wanting. In this case the accumulated matter makes room for itself among the abductor muscles, and forms a bulging elastic tumour on the inner aspect of the thigh close to the perinæum.

MATERIA MEDICA AND THERAPEUTICS.

EBSTEIN ON THE TREATMENT OF DIABETES MELLITUS BY SALICYLATE OF SODA.—Professor Ebstein, of Göttingen, reports the following cases in the *Berliner Klinische Wochenschrift*, for June 12, 1876, no. 24. He first alludes to the success obtained by Müller and himself in some cases of diabetes by the use of carbolic acid (see no. 49 of the same journal for 1873, and no. 5 for 1875). He strongly urges that diabetes is simply a symptom of very different pathological processes; and as its cause may differ, so various remedies may be used, and may succeed at different times. The chemical relations of carbolic acid and of salicylic acid induced them to make trial of the latter. This trial was not successful (perhaps because the dose was too small, only 0.3 to 0.5 gramme = $4\frac{1}{2}$ to $7\frac{1}{2}$ grains per diem being given). In this case only a trace of carbolic acid, into which it was supposed the other was decom-

posed, could be detected in the urine distilled with hydrochloric acid, by adding bromine solution to the distillate. After the salicylic acid failed, carbolic acid proved completely successful, the patient being cured by it. The present paper relates the history of two cases of diabetes, in the first of which carbolic acid and other remedies proved unsatisfactory, but salicylate of soda completely removed the diabetic symptoms; while, in the second case, there was considerable improvement from the same remedy.

Case 1. Ludwig F., of Göttingen, a brushmaker, aged fifty-eight, came under treatment on December 26, 1875. Except for a nervous fever twenty-five years previously, his health had been good in early life. After this fever, especially of late, he had suffered from transitory attacks of vertigo. There was no history of diabetes nor of neuroses in his family. For the last fourteen days, without obvious cause, he had increased thirst, increased flow of urine, great weakness, and prostration. For some days he suffered pain in the course of both sciatic

nerves, the tender points corresponding to the exit of these nerves from the pelvis. These pains vanished in less than a week after blistering. Sleep was imperfect, since the patient was forced to pass water every two hours. He was of medium size, and powerful build, with moderate corpulence, rapidly diminishing since the attack. His muscles were flabby and wasted. He had a sweetish insipid taste in the mouth, and his appetite was bad. Thirst was greatly increased. Bowels regular. No dyspepsia was complained of. The tongue was slightly coated. Physical examination of chest and abdomen only disclosed dulness without alteration of breath-sounds at the apex of the right lung. On December 27 he passed quite nine pints of urine in twenty-four hours, of sp. gr. 1.030, with 6,236.2 grains of sugar. No inosite was found by Cooper Lane's process.

The following table (abridged by the omission of maxima and minima from the one given by Ebstein in the original) will give an idea of the different modes of treatment resorted to in this case, and the various results obtained.

Date	Quantity of Urine in twenty-four hours, with its Specific Gravity	Sugar eliminated in twenty-four hours	Treatment and Diet	Results
1.—Dec. 28, 1875, to Jan. 2, 1876. (Six days)	4258 c.c. = 6½ pints. Sp. gr. 1031. The maximum was 9 pints	191.1 grammes = 2938.6 grains	15½ grains of carbolic acid dissolved in 300 times that quantity of water to be used in three days. Diet nearly all starchy; potatoes and bread	Considerable reduction of sugar. No change in quantity of urine or sp. gr.
2.—Jan. 3 to 14, 1876. (Twelve days)	1603 c.c. = 2½ pints. Sp. gr. 1025. Maximum = 90 ozs.	45.2 grammes = 697.5 grains	Same drug. Exclusively milk diet (well borne by stomach)	Very considerable improvement in all the symptoms
3.—Jan. 15 to 27, 1876. (Thirteen days)	2684 c.c. = 84 ozs. Sp. gr. = 1033. Maximum, 5 pints	136.4 grammes = 2106 grains	Treatment same as regards carbolic acid, now made 7½ grs. per diem. Mixed diet without potatoes. Milk diet refused by the patient	Not so good as 2, though better than 1. Perhaps from not allowing potatoes
4.—Jan. 28 to Feb. 10, 1876. (Fourteen days)	3141 c.c. = 98 ozs. Sp. gr. 1030. Maximum 6 pints	174.9 grammes = 2700.5 grains	Daily one flask of Carlsbad water. Mühlbrunnen (natural spring.) The same diet	A little better than No. 1
5.—Feb. 11 to 17, 1876. (Seven days)	3241 c.c. = 101 ozs. Sp. gr. 1032	169.1 grammes = 2463 grains	7½ grains carbolic acid per diem. Same diet	Similar. Carbolic acid showed no striking results
6.—Feb. 18 to 29, 1876. (Twelve days)	1429 c.c. = 45 ozs. nearly. Sp. gr. 1026. Maximum 56 ozs.	25.9 grammes = 400 grains. The minimum was total absence of sugar.	77 grains of salicylate of soda per diem in three doses [154 grains on first day produced vertigo, faint feelings, and noises in ears.] Same diet	Rapid improvement and vanishing of all the diabetic symptoms

Professor Ebstein appends the following table of the daily quantities of urine and sugar from the very commencement of the treatment by salicylate of soda. [It has not been thought necessary to convert the weights, as the results show equally well in the original form.—*Ref.*]

	C.c.	Grammes.
Feb. 17 . . .	3675	with 190.8 of sugar per diem.
" 18 . . .	1800	" 77.4 " "

	C.c.	Grammes.
Feb. 19 . . .	1800	with 64.8 of sugar per diem.
" 20 . . .	1800	" 64.8 " "
" 21 . . .	1300	" 44.2 " "
" 22 . . .	1575	" 51.8 " "
" 23 . . .	1300	" 13.1 " "
" 24 . . .	1575	" 21.9 " "
" 25 . . .	1300	" Traces " "
" 26 . . .	1300	" 1.7 " "
" 27 . . .	1300	" Traces " "
" 28 . . .	1300	" Do. " "
" 29 . . .	1300	" None at all " "

From this time no more sugar appeared in the urine, and the patient gained weight and strength. He had had boils in January. No sugar was observed in the pus of these boils. In a note we are told, under date of May 30, 1876, that the patient takes a mixed diet, and continues to gain weight, the urine being quite free from sugar, and not excessive. By way of precaution he takes fifteen and a half grains of the salicylate of soda daily even now.

Case 2. In the second case, a merchant, aged fifty-three, had suffered from diabetes from 1867. He was rather a scrofulous child; had a 'sort of brain-inflammation' in 1847, when a student; and in 1866 a severe inflammation of the cæcum. The diabetes came on some months later with lassitude, and pains in the region of the kidneys. Thirst was increased, but hunger was never very immoderate. In 1871 the patient recovered from a severe pneumonia; some years previously he had a sharp attack of dysentery. From the beginning of the attack to the spring of 1875, the daily quantity of urine was about four pounds in twenty-four hours; since then it rose to about seven pounds. Till 1871 the percentage of sugar was about $1\frac{1}{2}$ to 23. In 1874 the sugar rose to 4 per cent. In 1875 to 5.8 per cent. Carlsbad, in 1871 and 1874, and Neuenahr, in 1872, 1873, and 1875, never completely cured him of the glycosuria, though he was always better for these 'cures.' For some time he had taken 'Uslar's syrup,' which contains iron. The patient was bald, and suffered from seminal emissions. Present weight 153 pounds; sleep bad; dreams disturbing; crawling feelings in limbs. On December 21 he was taking mixed diet with potatoes, passing 109 ounces of urine in twenty-four hours with 4 per cent. of sugar in the day, and 4.3 per cent. at night. Ebstein says that diabetic diet at once reduced the quantity of urine to seventy-eight ounces, and the percentage of day urine to 1.8, of the night to 2.9 per cent., the total quantity of sugar being about 13 ounces. He disliked this diet, and soon left it off, but was persuaded to give up potatoes. He was then placed upon carbolic acid, with only slight benefit. He was therefore placed upon salicylate of soda, at first in doses of ten grammes (155 grains nearly) per diem. This quantity, however, produced similar unpleasant feelings to those mentioned in the former case. It was therefore reduced to one-fourth that quantity, and afterwards increased to forty-six grains per diem. Under the use of this, the urine was reduced to nearly normal (sixty-four ounces per diem), and the sugar reduced to half its former quantity. He also gained weight, but was not cured. W. BATHURST WOODMAN.

SÉE ON THE TREATMENT OF ANGINA PECTORIS.—The *Moniteur Thérapeutique* gives an account (quoted in *Paris Médical*, April 13, 1876) of some recent observations of Professor Sée on angina pectoris. According to him, this affection is not a neurosis, but an ischaemia combined with pain. The treatment should therefore be twofold. As the pain, which by its violence stops the breathing, can kill the patient in a few minutes, it is to it that we must first address ourselves when called during an attack; and we must not trust to ordinary means, which would probably act too slowly; we must immediately administer a hypodermic injection of one to two centigrammes (0.15 to 0.3 grain) of morphia. This injection, moreover, should be repeated one to three times a day, and continued at least twice in the twenty-four hours, for some weeks,

until the attack has completely disappeared. Without this we shall see it reappear, and shall lose all the benefit of the remedy.

With respect to the ischaemia which we are about to mention. The morphia acts not only by suppressing the pain; it assists the circulation also, and thus directly addresses itself to the ischaemia which, stopping the heart from receiving sufficient blood, it causes to lessen. Together with these morphia injections, we ought to give chloral enemata. By the mouth this remedy will not be borne in these cases, and it seems besides to be more easily absorbed by the rectum. This is the formula of M. Sée:— \mathcal{R} Chloral, 2 to 3 grammes; mucilage, q.s.; water, 150 grammes. Make an enema. Chloroform should be completely banished from the treatment of angina pectoris, because it favours arrest of the heart. Nitrite of amyl has no action as a sedative, but it may perhaps be useful, because it dilates the vessels. Belladonna produces no effect; and as for antispasmodics, they are absurd in a case so serious and urgent. Acetate of ammonia has a certain value as an excitant of the circulation, and because it acts at the same time on the respiration; but it is not so valuable as the morphia. External measures, as cupping, heat, frictions, etc., have no value; nevertheless, we are sometimes obliged to use them in deference to prejudice. To prevent a return of the attack, we must have recourse to bromide of potassium or digitalis. During the attack the use of bromide would be absurd, because it contracts the vessels instead of dilating them; besides, its action would be too slow; but in the interval it serves, like digitalis, as a regulator of the circulation and the respiration. Arsenic, much vaunted, does no good. Hydrotherapy is highly dangerous, and its employment can only be explained on the idea that we had a neurosis to deal with. With this method of treatment, either a return of the attack or cerebral congestion is to be feared.

LA SALUTE ON A POWDER FOR THE PREVENTION OF CICATRICES FROM VARIOLOUS PUSTULES.—The author in this paper (*Paris Médical*, June 1, 1876, from *La France Médicale*) says he has proved in many cases the good effects of a powder composed of four parts of flowers of sulphur and one part of red precipitate. He has been able by the aid of this topical application to prevent the formation of evident cicatrices on the face of a variolous patient. He was led to the application of this mixture in cases of confluent small-pox, by the success which he had obtained with it in many forms of disease of the skin, particularly eczema and acne. This powder should be placed on a slight layer of glycerine previously spread on the pustules which have come to the point of suppuration. The glycerine ensures the adhesion of the powder, which dries it up, forms a crust, and falls off, leaving the skin free from cicatrices.

HIRTZ ON THE ACTION OF REMEDIES.—M. Hirtz has just published, in the *Bulletin de Thérapeutique*, a remarkable article on this subject. It may be summarised as follows (*Paris Médical*, June 1, 1876). The disease must not be considered as a concrete body, superadded to the organism, nor even as a lesion, but as a physiological act, perverted from the normal type. The remedy should be considered as a substance or agent, capable of bringing back to the normal type the perverted organic function.

Consequently, the virtual value of a remedy ought to be deduced not from the disease, as a whole, nor from the 'brutal and unintelligent' fact of the cure or final insuccess, but from its modifying action on such organs or such a function, or (exceptionally in the case of specifics) from its clinical influence on certain morbid forms. The calculation of dynamic action, the determination of therapeutic action, and the appreciation of the final result, can only rest on these elementary acts. For the formation of a rational, scientific, therapeutic system, a complete knowledge of the physiology of the disease and the physiology of the remedy is necessary in order to modify the one by the other. This method, which may be called analytic therapeutics, is the only true scientific and progressive one; and the other, which takes as its criterion only success or the reverse, constitutes a retrograde, fruitless, therapeutic system, which is called empiricism and mesmerism.

LIMOUSIN ON THE EMPLOYMENT OF SALICYLIC ACID IN THE PREPARATION OF HYPODERMIC INJECTIONS.—M. Limousin recently presented to the Société de Thérapeutique (*Paris Médical*, April 20, 1876) some specimens of solutions for hypodermic injection, prepared according to the method of M. Patrouillard, with distilled water of the spiræa ulmaria. The spiræa ulmaria contains a principle analogous to salicylic acid, and it is to this principle that is probably due the property of preserving unaltered for a longer or shorter time the solution of organic alkaloids. But this article does not always arrest the development of algæ and confervæ. Therefore M. Limousin thought of substituting for it a solution of salicylic acid (1 to 2,000) and has found it work well. A solution of hydrochlorate of quinine in ordinary distilled water at the end of some weeks was full of germs, while another solution of M. Limousin's liquid, made at the same time, was still unaltered. Clinical observations are yet required as to the innocuousness to the cellular tissue of this injection liquid; *a priori*, however, we can imagine that a solution of salicylic acid in the proportion of 1 to 2,000 is altogether harmless. M. Dujardin-Beaumetz employs, as a solvent for the alkaloids, distilled cherry-laurel water; solutions made with this liquid keep well, and have no irritant action on the tissues.

W. DOUGLAS HEMMING.

KLINK ON THE DETECTION OF MERCURY IN HUMAN MILK DURING INUNCTION WITH MERCURIAL OINTMENT.—Dr. Edward Klink relates (*Vierteljahrsschrift für Dermatologie und Syphilis*, 1876, 2 Heft.), the case of a syphilitic woman who was nursing her child, undergoing an inunction cure, during which mercurial ointment was rubbed into the skin twenty-five times. After the thirteenth inunction, milk was taken daily for chemical examination, about eleven ounces altogether being received. The proof that the milk contained mercury was unequivocal. Observers who had come previously to a negative conclusion had employed insufficient methods in the analysis.

In the case of this woman, syphilitic symptoms present in the child disappeared during the inunction treatment.

COCA.—The *Edinburgh Medical Journal* publishes the following curtailed notice of a review of a work on this subject in the *Revista Médica de Chile* for November last. 'In the last number of this review, we mentioned that the Medical Society had

been presented with a beautiful work on this interesting plant by Dr. Manuel A. Espinosa. To-day, having read it attentively, we wish to give a succinct account of it. After a very curious history of the plant in question, which abounds in most interesting data, which reveals in its author great erudition, and a spirit of extensive and conscientious investigation, after a complete and perfect botanical description, and after enumerating the localities in America where it is found or where it is cultivated, he enters into the question of its qualities, which is undoubtedly the part on which he is best qualified to speak, and which is also the most worthy of notice. He cites various analyses of coca leaves, which are made up of, according to Miemann, of cocaine, of a particular kind of wax, tannic acid, solid essential oil, chlorophyll, and woody matter. He does the same with the *llipta* or alkaline matter, which the Indians who use it mix with the coca leaves. This is made into a bolus, which they call *acullico*, and which must be chewed in order to extract from the leaves their active principle. He attributes to the cocaine the effects which the chewed leaf produces on the body. Cocaine is a nitrogenous alkaloid, able to neutralise acids, and which forms with them crystallisable salts, especially with acetic and hydrochloric acids, and whose atomic formula is $C_{16}H_{20}NO_4$, and an equivalent of water. The action which *llipta* produces on the coca is thus perfectly explained; the cocaine existing in a state of combination with organic acids, any alkali or alkaline carbonate will loosen it from its combination, thus favouring its solution in the saliva, and its ultimate absorption. As cocaine is very soluble in alcohol, and especially so in ether, the best pharmaceutical preparation of coca will be the ethereal alcoholic tincture. With the object of making observations worthy of credit, he made experiments on his own person and on a medical student, who willingly lent himself for experimentation. Wishing specially to discover its influence on tissue waste, at the same time they made use of an identical alimentation, and each day carefully observed the quantity and quality of the excretions, specially the pulmonary and the urinary. During the twenty-six days the observations lasted, they noted the temperature of the body and the state of the chief organs. They did not notice the absolute loss of appetite which is attributed to the use of coca, still less the hallucinations, full of poetry, which Dr. Mantegazza has described with as much exaggeration as enthusiasm. Thus, the *coquero*, believing himself transported to a thousand and more diverse worlds, mounted on two leaves of coca, exclaims: 'God is unjust for having made man able to live without coca. I would prefer a life of ten years with coca to one of ten thousand centuries without it.' Neither did they feel that irresistible desire to skip about, which other observers say they have noted, which incited them (according to their own relation,) to jump over the heads of persons round about them. The only thing they could observe with exactitude was a slight headache, a sensation of heat in all the body, and sleeplessness. Their strength and energies seemed to be augmented. The daily examination of the urine, and of the product of the pulmonary exhalations, was an objective point of the experimentation. The quantity of urea in the urine, and of the carbonic acid in the expired air, underwent a notable increase, both phenomena being preceded by acceleration of the pulse and the respiration, and by a slight augmentation of temperature. Dr. Espinosa looks

upon coca as 'a special stimulant of the nervous system, whose gentle and continuous action is quite characteristic.'

TOXICOLOGY.

STEVENSON ON NITRO-BENZOL POISONING.—Dr. Thomas Stevenson has printed the following case in a pamphlet form. It is, as he justly says, almost, if not quite, unique, nitro-benzol having been taken by an adult man, in measured doses, until the full physiological, and well-nigh lethal effects of the poison were produced. The symptoms were well marked, and the delayed or cumulative effects of the liquid were very apparent. The original is accompanied with a lithograph of the prescription, through the misreading of which the case occurred; and also another prescription, written for the same patient by the same physician. They are both curiosities in the way of illegibility. The first of these prescriptions is somewhat of a favourite with the prescriber, and has frequently been misread; the true reading, 'Benzole Rect.,' being sometimes taken for 'Bismuth Nitr.' The patient, Mr. Sydney S—, aged twenty-one, married, consulted a physician in November 1875 for a pain in the chest, troublesome cough, and free expectoration. He had previously been healthy. Strychnine was prescribed as a tonic, and subsequently the following mixture:—

R. Benzole Rect. ʒij
 Ol. Ment. pip. ʒss
 Ol. Olive, ʒ x, gutt. xxx t.d.s.

He was requested to have the medicine dispensed by a particular druggist. This was done, and the cough was relieved. In February he again had occasion to take the medicine, and had it made up at another chemist's, where it was misread, and nitro-benzol given instead of rectified benzol. On February 21, Mr. S— took three doses of thirty drops = 20 minims; on February 22 three more doses, and on the next day one dose at 9 A.M., or in all about 23 minims of nitro-benzol, the interval between the first and last doses being forty-eight hours. On the afternoon of the 22nd, he was observed to look a little pale and weak, but he was not conscious of feeling ill till after taking the final dose at 9 A.M. on the 23rd. All that morning he suffered from headache. At 1 P.M. he had his dinner, after which he

went from the City to Islington, and back again to the City. His fellow-clerks said he looked ill, and advised him to go home. He left the office shortly after 2 P.M., but had not walked more than forty yards, when he fell down. He was just sensible enough to state where his office was situated, but speedily became quite unconscious. Mr. Gross, a student of Guy's Hospital, saw him at 3.15 P.M. He appeared to be dead. The surface was bluish-purple and cold. No pulse could be felt at the wrist. The lower jaw was rigidly closed, but the limbs were flaccid, and dropped powerless when raised. The heart could, however, be heard, beating faintly and irregularly. The pupils were widely dilated. No breathing could be perceived till twenty minutes after Mr. Gross first saw him. Sinapisms, and friction to the limbs were used; and after an hour, when consciousness had partly returned, secondary magneto-electric current was sent through the hands and upper limbs. This brought on vomiting, and seemed to stimulate the heart. The vomited matter smelt strongly of nitro-benzol. It consisted of the remains of an abundant meal. The bowels acted without his consciousness. Between 5 and 6 P.M. he was admitted into Guy's Hospital, under Dr. Moxon. He was then nearly insensible; the pulse was very weak and irregular, and could not be counted. Brandy was administered, and ammonia inhaled. About 7 P.M. he began to be conscious, and could then remember all that occurred before 2 P.M., but nothing subsequently. He also complained of headache. At 9 P.M. the skin was still very blue, and the headache persisted. Pulse very irregular. From this time he made a satisfactory recovery, and by the middle of next day was fairly convalescent. Eight fluid-ounces of the urine, collected on the morning after the onset of violent symptoms, and after convalescence was well established, were agitated with chloroform, and a residue was left after evaporation of the chloroform, smelling strongly of nitro-benzol. When the true nature of the case was recognised, the remainder of the medicine in the bottle was examined, and its composition determined. Dr. Stevenson notes how closely the symptoms approximated to those produced by prussic acid.

OPHTHALMOLOGY AND OTOLOGY.

POLITZER ON THE PATHOLOGICAL HISTOLOGY OF THE LINING MEMBRANE OF THE MIDDLE EAR.—Professor Politzer, of Vienna, describes, in the April number of the *Archiv für Ohrenheilkunde*, the appearances he has found in his microscopical examinations of the lining membranes of the middle ear, when suffering from chronic inflammation, with perforation of the tympanic membrane. One preparation showed an extensive net of distended lymphatic vessels, whose varicose turgid branches either crossed or anastomosed with each other, and here and there ended in thick club-like culs-de-sac. The inner walls of these vessels had an epitheloid

lining. In the neighbourhood of these vessels were seen round or oval cyst-like spaces, with a double contoured wall, showing a fibrous structure, and containing cells like lymph-corpuscles. Politzer believes that these vessels have existed in the normal state of the membrane, and are now only distended and changed in form.

In the case of a patient who died of phthisis, after suffering from a chronic otorrhœa, which had caused a high degree of deafness, he found the tympanic cavity filled with a connective tissue growth. A microscopic examination of this growth disclosed a tissue with vessels and cyst-like bodies, similar to those described in the previous paragraph. Sections through the drum, the growth, and the inner wall of the tympanic cavity at different places, showed that at the periphery of the drum the original tissue of which it was composed was separated sharply from the growth, while at the centre of the drum, where there had formerly been a perforation, the true tissue of the membrane failed entirely, but its place was taken up and completely filled by the pathological formation, which at this spot was covered on the external side by several epithelial layers.

W. LAIDLAW PURVES.

LADREIT DE LACHARRIÈRE ON HERPETIC AFFECTIONS OF THE EAR CAUSING DEAFNESS.—Under this title, in the *Annales des Maladies de l'Oreille et du Larynx*, Dr. Ladreit de Lacharrière describes two common maladies—eczema and pityriasis. Eczema manifests itself on the ear in its simple and compound forms, impetiginous eczema and herpetiform eczema. This affection may be recognised by the following characters: redness of the diseased surface; persistent itching; secretion of a lemon-coloured secretion, staining and stiffening the linen; a punctated state of the skin, produced by the inflamed orifices of the canals of the ceruminous glands. This affection, most common in women when very young or at the critical period, causes a deformity of the auricle; causing permanent secretions from the meatus, it provokes an alteration of the walls as far as the surface of the tympanum, and by the swelling may often obstruct the meatus.

Chronic eczema causes at length lesions of the middle and internal ear, and with it deafness, buzzings, musical sounds, and hissings. Eczema is often favoured by lack of hygienic care, want of cleanliness, and is very often respected by parents as being salutary. Consequently it often presents itself as an inveterate affection. Eczema of the ear is particularly obstinate. M. Ladreit de Lacharrière has never seen it disappear spontaneously. When the eczema is acute, warm lotions of marsh-mallow and poppy-heads may be prescribed several times a day. After each of these, a poultice may be applied, of a mixture of equal parts of oil of sweet almonds and oil of henbane. These applications soothe the itching. Frequent saline purgatives may be given. At the end of some days, if the disease tend to pass into a chronic condition, the emollient lotions may be replaced by alkaline lotions; these solutions may be gradually increased in strength, commencing with a teaspoonful of bicarbonate of soda in a glass of warm water.

The author rejects the application of ointments, which stop the discharge of fluids while the disease occupies the auditory canal. For tar he prefers a solution to an ointment, and injects this solution

three times a day. He does not employ starch-powder. If the disease be obstinate, he does not hesitate to treat it by cauterisation. He employs for this purpose the following solution: R Rose water, 30 grammes (about 1 ounce); nitrate of silver, 4 grammes (1 drachm); laudanum, 1 gramme (15 minims). He absolutely forbids the employment of blisters, advocated in eczema, in children; they spread the disease without curing it. The general treatment should always keep pace with the local. All indigestible food must be avoided, and two baths a week of starch and gelatine may be given; in scrofulous subjects, sulphur baths; in rheumatic subjects, alkaline remedies.

Sometimes neither scrofula nor rheumatism is present, but the disease presents a true herpetic character. We must then have recourse to the following remedies: arsenic, iodide of potassium, and mercury. In a vigorous subject, the author prescribes Wendt's powder; R Calomel, 20 centigrammes (3 grains); yellow sulphide of antimony, 20 centigrammes (3 grains); white sugar, 8 grammes (2 drachms). Make into twelve powders; one powder to be taken three times a day.

REPORTS OF FOREIGN SOCIETIES.

MEDICAL SOCIETY OF BERLIN.

January 18, 1876. *Vesical Calculi*.—Dr. Fürstenheim showed some specimens of vesical calculi, taken from a subject on whom he had made a *post mortem* examination. The patient, a man, aged seventy-seven, was first seen by him in November, 1874. He had for several years suffered from vesical catarrh, probably connected with hypertrophy of the prostate, which developed itself more in the direction of the urethra and bladder than of the rectum. Up to 1869 no local treatment was adopted, although the patient was always in a miserable condition from incontinence of urine. After this time the catheter was regularly employed, and injections were made into the bladder. The catarrh, which appeared to have been moderate when the catheter was first used, afterwards increased in spite of every precaution. In the autumn of 1873, while the patient

was catheterising himself with an elastic catheter, a piece more than two inches long broke off, and remained in the bladder. He consulted a well-known surgeon, who (Dr. Fürstenheim thought, wrongly) advised that no attempt at extraction should be made. The patient then endeavoured to find by experiment what would become of the piece of catheter in his bladder; he placed the other portion of the instrument in a vessel filled with his urine, which was renewed daily for a quarter of a year. He found that the catheter was not incrustated with urinary salts, but became brittle, and could be broken down with the finger. The presence of the foreign body soon became manifest in the bladder; and in about a year the patient's suffering had greatly increased. When Dr. Fürstenheim first saw him, in November, 1874, he did not find in the bladder a free smooth piece of catheter, but a rather rough, not hard, movable calculus, having about the length and thickness of a little finger. There could be scarcely any doubt that the piece of catheter was the nucleus of this calculus; and it was evident that it must be broken up within the bladder. Lithotripsy was performed twice in the course of eight days, without anaesthesia, and was very well borne. Only some very small particles of the material of the catheter and some phosphatic gravel were removed by the instrument or washed out of the bladder. The operations were followed by scarcely any constitutional reaction, and the patient felt so much relieved that he believed that he was freed from his trouble. In April, 1875, Dr. Fürstenheim found an immovable stone in the bladder, probably lying in a diverticulum. In December, 1875, the patient died; and a *post mortem* examination was made by Drs. Fürstenheim, Zober, and Cholewa. The bladder was excentrically hypertrophied; there was no ulceration, and the trabeculae were moderately developed. In a small diverticulum was an elongated calculus, one of the rounded ends of which reached to the entrance of the diverticulum. There were also seven calculi in the bladder; four being roundish, about the size of small chestnuts, and three flatter. In addition, there was a larger calculus three centimetres (1·2 inches) long, the nucleus of which was formed by the piece of catheter, a portion of which was apparent at one end. The smaller elongated calculus above mentioned also contained a portion of the catheter; and small particles of it were also found in one of the round stones. Dr. Ewald found the calculi to consist of uric acid and urates in abundance, triple phosphate, cystin, and perhaps also xanthin. The elongated calculi were not so hard as the others, and appeared to consist mostly of phosphates. Dr. Fürstenheim also observed two other calculi; one oval, the other consisting of concentric layers, and explained the differences between them and the other calculi which he exhibited. He said that the differences depended on the constitution of the urine and the consequent chemical composition of the stone, on the shape and kind of the nucleus, on the positions of the calculi with respect to each other when several were present, and on the condition of the bladder. He thought that it would have been scarcely possible for a large oval calculus to form in the bladder of the patient whose case he had described; this was interfered with by the frequent use of the catheter, and there could be no question that the wall of the bladder had an influence on the form of the calculus. He also believed that the composition of the urine depended more on the condition of the bladder in some

circumstances than was generally assumed. It was not only that the urine became stagnant in a paralysed bladder, and became decomposed under the influence of pus, mucus, and blood, but especially when the mucous membrane of the bladder is more or less diseased and ulcerated, there is an interchange of the salts and other matters in the stagnated urine with the saline matters of the fluids present in and between the tissues of the diseased bladder. This change in the urine deserved to be made the subject of experiment; but it must affect the composition of the stone in course of formation. As regards the removal of foreign bodies from the bladder, statistics had been collected by Civiale, Denucé, and Porta; the general conclusion derivable from which was, that we should not hesitate to attempt the removal through the natural passages or through a fistulous opening if one were present, unless any strong contraindication existed, such as inflammation of the urinary organs. Of 391 cases collected in twenty years by Denucé, there were 225, in which no attempt had been made to remove the foreign body, either by lithotomy or by bloodless extraction; and of these 20 or 11 per cent. died sooner or later from the direct effects of the foreign body. Of 83 individuals in whom extraction was performed without lithotomy, only two or three died. When extraction was impossible, the question arose whether the foreign body should be left to itself, or whether lithotomy should be performed. Denucé had raised his number of cases to 420; in 37 of these (14 being males) the foreign body was discharged spontaneously. Dr. Fürstenheim had some years ago described a case in which a broken piece of catheter was expelled from a man's bladder. He also knew an old lady from whose bladder a stone nearly as large as a pigeon's egg was spontaneously expelled. The common idea that foreign bodies are more frequently met with in the female than in the male bladder was not correct; it was indeed true as regarded such articles as medallions, forks, pepper-boxes, etc., but not as regarded broken bougies and catheters. According to Denucé, of 61 persons on whom lithotomy was performed for the removal of foreign bodies, 31 or 51 per cent. died; and of 225 cases collected by Porta, cystotomy was performed in 122, with a mortality of 20 per cent. Where simple extraction cannot be effected, the choice between doing nothing or performing lithotomy must depend on the circumstances of the case. Fortunately, the invention of lithotripsy and the construction of improved instruments had rendered the removal of foreign bodies from the bladder much easier than it previously was. According to Denucé, up to 1830 there were 100 cases of lithotomy for the removal of foreign bodies and only twenty-seven of extraction by the natural passages; while after that year there were 122 cases of natural extraction and only twenty-one of lithotomy. In future, lithotomy would become still less frequent in such cases. It was sometimes very difficult, indeed impossible, to seize a foreign body in the bladder. Some smooth elastic catheters could not be readily distinguished by the feel from the trabeculae of the bladder. The search must, therefore, be made carefully, and, in case of failure, must be repeated soon, and not put off. While the foreign body not unfrequently remained bare (this occurred in 87 out of 138 cases described by Porta), it is often found encrusted in the course of a few months, and may then be readily seized and broken up.—Herr Senator remarked with

respect to the interchange between the urine in the bladder and the blood and tissue-pores of the organ, that experimental researches had been made by Treskin and others, which showed that urine retained in the bladder lost urea and frequently became richer in salts. Under pathological changes attended with dilatation of the vessels, or where ulceration was present, such interchange might still more easily occur.—Herr Fürstenheim replied that Meckel had already spoken of such an interchange, but had only suspected it. He considered it especially desirable that investigations should be made as to the influence of a previously diseased vesical mucous membrane.—Herr Seligsohn said that incrustation of foreign bodies in the bladder had been experimentally demonstrated, especially after the use of drinks containing lime.—In reply to a question from Herr Güterbock, jun., Herr Fürstenheim said that he referred only to foreign bodies in the bladder, and not to those in the urethra.

Pathological Anatomy of the Eye.—Herr Hirschberg read a paper on this subject.

Experimental Researches on Fever.—Herr Senator said that Dr. Jacobson's observations confirmed to some extent the conclusions at which he had arrived, inasmuch as he found that the cutaneous temperature in fever underwent remarkable oscillations. While he did not believe that warmth or coldness of the skin indicated in all circumstances dilatation or contraction of the vessels, the conclusion that this connection existed was justified by the circumstances under which Herr Jacobson's observations were made. Herr Jacobson had alleged, as Herr Senator had inferred from experiments on animals and from chemical observations, that the cutaneous vessels were neither paralysed nor tetanically contracted; but he left it undecided whether Senator's further conclusion, that in most febrile conditions the vessels were abnormally irritable, was correct. Herr Senator found, independently of the reasons which he had already adduced, that the observations made by Herr Schülein, at the suggestion of Herr Jacobson, indicated an abnormal irritability or an abnormal irritation of the vessels in fever. While the temperature measured between the toes of a healthy person showed variations not exceeding 5° or 6° Cent. (about 9° Fahr.), the differences in febrile patients amounted to 10°, 12°, or 13° C.—Great oscillations might be observed even in a healthy person under certain circumstances: for instance, in one who, having cold feet, took a warm foot-bath.—Herr Jacobson did not dispute the fact that in certain febrile diseases there was increased irritability of the vessels of the skin; but, having in view a statement of Charcot, that Woodman had found variations of 8° or 10° in the temperature between the toes of healthy persons, he did not feel justified in assenting to the further conclusion of Herr Senator. To his remark that the changes of the cutaneous temperature did not always correspond with the oscillations in the vessels, he replied that it did not appear to him plausible that during febrile heat the vessels in a portion of the skin should contract while the temperature of the part rose, and *vice versa*. Against the method of thermo-electric measurement, there was, perhaps, the objection that the insertion of the needles, however fine they might be, into the superficial layers of the skin, might produce irritation of the sensory nerves and reflex changes in the lumina of the vessels. He had not, however, observed this action to be produced; it would be

indicated by paleness or redness in the neighbourhood of the irritated part. As regarded withdrawal of heat by full baths at a temperature of 14° R. (63.5° Fahr.) advocated by Liebermeister and Jürgensen, he considered that so great a divergence between the external and internal temperatures was not only irrational but dangerous.—Herr Seligsohn did not agree with this objection against the reduction of temperature. In the measurements reported there were two distinct factors; one only of which, the temperature in the axilla, which indicated the temperature of the blood, came into consideration here. The blood being regarded as the seat of tissue-change, it was correct to use means for the withdrawal of heat when its temperature was abnormally high. The good results obtained in typhus by cold baths—even though not always at 14° R.—spoke in favour of the practice. He doubted whether very disadvantageous results had been thus produced.—Herr Jacobson said that a febrile temperature in the axilla could not be taken as a measurement of the intensity of the oxidation process, inasmuch as it might not depend on increased production of heat, but on diminished loss of the heat. During rigor, there was an increase of the temperature in the axilla, and yet Herr Seligsohn would not give a cold bath in this condition. There could be no question as to the danger of producing collateral fluxions to internal organs, and especially intestinal hæmorrhages in enteric fever.—Herr Senator said, as regarded the unlimited employment of the energetic withdrawal of heat, that he believed, and had expressed the opinion several years ago, that this must of necessity produce a fluxion to internal organs. The advocates of this practice attached much importance to the after-effect, many of them believing that during a bath the production of heat was increased in a certain ratio to its withdrawal. This view, however, was quite untenable. As regarded the different conditions of the vessels accompanying changes in the cutaneous temperature, he could very well believe that a cold skin might exist with dilated vessels; an example of this was shown in venous stasis and in cyanosis. Further, in some so-called adynamic fevers, in many states of febrile collapse, the skin was often found warmer than normal, especially on the body. It might also be thought that in fever, when the skin had become hot and an irritation was suddenly applied to the vaso-motor apparatus, producing contraction of the vessels, the skin would remain warm for some time, deriving heat from the subjacent layers of tissue.—Herr Wiss said that the statement of Herr Senator, that the temperature of a febrile patient might rise while he was in the cold bath, was confirmed by some observations of Thompson, of New York, who used large air-cushions with entrance and exit tubes, through which a stream of cold water was constantly kept flowing.

February 9. *Sarcoma of the Kidney in an Infant.*—Herr Baginsky showed a case of sarcoma of the kidney in a child seven months old. It had suffered for several weeks from intermittent attacks of hæmaturia, which often coloured its linen red. On examination, a tumour was found in the left half of the abdomen, extending from the border of the ribs to the middle line in front and downwards to the crest of the ilium. The urine contained much blood, and the proportion of red and white corpuscles was normal; so that the idea of a leukæmic swelling was excluded. The character of the urine led to the almost certain

diagnosis of a renal tumour. The tumour increased in size; and from time to time a portion of intestine—apparently the colon with the rectum, pushed forward by the tumour—appeared below the umbilicus, somewhat to the right of the middle line. Fluctuations became perceptible in the tumour; and, dyspnoea being urgent, a puncture was made on the left side by Dr. Baginsky and Dr. Schadowald, which gave exit to 470 cubic centimetres of a dark beer-coloured fluid. It contained much blood; and urea and uric acid were found in it by Herr Mühsam. The child had vomiting and green stools, and died the day after the puncture. At the necropsy, there was found to be great anæmia of all the internal organs. The left kidney was converted into a cystoid tumour consisting of two parts, a large cyst containing fluid, and a firmer mass almost as large as a child's head. The descending colon and rectum passed almost perpendicularly over the tumour from the umbilicus to the pelvis. The tumour was adherent to the abdominal walls and to the diaphragm; the mesentery and its glands were unchanged. The tumour was found by Dr. Virchow to be a spindle-celled sarcoma. In it there were some small remnants of the kidney, containing numerous tubules with normal epithelium. The right kidney presented well-marked parenchymatous nephritis. Dr. Baginsky had met with in literature several cases of medullary carcinoma of the kidney in children, but none of sarcoma. The later symptoms, vomiting and green diarrhoea, were probably of uræmic origin. No convulsions were observed.

The Operative Treatment of Pleurisy.—Dr. Ewald showed a patient, and made some remarks on the operative treatment of pleurisy. The case, he said, was not an extraordinary one, but it well illustrated the application of certain principles which he had been led to adopt by a hospital experience of fifteen years. On the resumption of the publication of the *Charité Annalen*, Dr. Frerichs had entrusted to him the preparation of a report on the subject. A table which he exhibited showed that from 1860 to 1875 there were 143 cases of serous effusion in the pleura with four deaths, or 2·79 per cent.; of these, puncture was performed in twenty-six, none of which were fatal, between 1870 and 1875. In other words, while from 1860 to 1870 there were seventy-eight cases with four deaths, or 5·12 per cent.; from 1870 to 1875 there were 115 cases, and no deaths. He believed that there was a general agreement among physicians that an operation should be performed in cases of serous pleurisy, when they had lasted on an average four weeks, and did not yield to internal treatment. The prognosis of purulent effusion was quite different from that of serous; and, while the mortality of the cases not operated on was so great, attempts had been made to improve the condition of operation proceedings. There was, however, a deficiency of statistics to show indications for the operation. Dr. Ewald believed that the results of the operative treatment of pleurisy had often been disappointing, because too much was expected. As long as favourable cases were published and unfavourable cases held back, a proper conclusion could not be arrived at from the facts presented. In the *Charité Hospital*, there had been forty-six cases of empyema, with a mortality of 56·52 per cent.; of these thirty-five had been treated by puncture or excision, of whom 54·28 had died, and eleven had been treated by medicine, with a death-rate of 63·63 per cent. The mortality was then

somewhat greater in the cases treated by medicine alone than in the others; the difference, however, was not so remarkable as might have been expected, or even as Dr. Ewald himself expected, before he revised his materials. With regard to the duration of the disease in the cases which were not fatal, it was found to be 5·2 months in the cases not treated by operation, and 6·2 months in those treated by incision. It was also generally assumed—and in itself quite correctly—that the fever, pulse, and respiration were improved by operation. But, in taking all the cases together, the influence as regarded these three factors was not so great as might be expected. Even though there be a reduction of the fever and an improvement of the pulse and respiration, oscillations sometimes occurred which were perfectly explicable by the fact that along with the pleurisy there was chronic disease of the lung, accompanied with fever, quick pulse, etc. As regarded 'cure,' nothing was said of this, as the definition of the term was difficult, and Dr. Ewald did not know always how his predecessors had interpreted it. The results were not very brilliant; and the question arose for consideration, what causes prevented operations on empyema from being so successful as the opening of abscesses in other parts of the body. Dr. Ewald believed that there were two; the hitherto too exclusive employment of puncture, and the too long delay of incision, either with or without puncture. It was manifest and easily intelligible if one remembered the physical conditions present, that when puncture was made only so much of the contents of the pleural cavity could escape as corresponded to a space which was filled by the neighbouring parts. At a very early stage in suppurative pleurisy, however, changes took place which prevented the quantity removed from being other than very small, the entry of air being prevented. The disadvantages of puncture as compared with incision were shown by the following statistics. Of thirty-five cases treated by operation, incision, generally preceded by puncture, was made in twenty-six, with a mortality of 46·15 per cent.; and in nine cases puncture alone was made, with a mortality of 77·77 per cent. Of the last nine, two only were cured, and that doubtfully. The disadvantage of too late incision was also shown by the same cases. In those in which the operation was made from the first to the thirtieth day, the death-rate was 37·5 per cent.; when it was made after the thirtieth day, it was 53·8 per cent. The duration of treatment in the two classes of cases was, as above stated, 5·2 and 6·8 months respectively. But, when the cases only were taken in which incision was performed within the first fifty days, the duration of treatment was reduced to 4 months instead of 6·8. If, from the thirty-five cases operated on, six were deducted in which there was opening of an empyema necessitatis, it appeared that the probability of success in the cases of puncture was 68 to 1,000, and in the cases of incision 528 to 1,000, and that, in all probability, puncture alone would fail in 928 cases out of 1,000, incision being at last necessary. Dr. Ewald believed that it might fairly be concluded from these observations that, in cases of empyema, incision should be performed as early as possible, and puncture thrown overboard altogether, or only employed as the first stage of the operation. The question now arose, when was empyema present? This, as had been already pointed out by Ferber and Quincke, could

only be ascertained by an exploring puncture. The signs derived from the external appearance, the course of the fever, etc., sometimes failed; serum being sometimes found where these had led to the expectation of pus, and *vice versa*. Puncture was most easily made with Pravaz's syringe, and, if the instrument were carefully disinfected, was quite harmless. As regarded the operation, the pleural cavity was opened by a puncture, or the tissues were gradually dissected down to the pleura, which was then opened. If the opening should become too small to allow the introduction of the necessary instrument for washing out the pleura, it was a good plan to resect a portion of a rib. In the latter stages, a modification of Lister's treatment had been employed with satisfactory results. It might be said that the statistics adduced represented a rate of mortality not met with elsewhere. Dr. Ewald, however, had already said that his results were not brilliant; but he believed that hitherto the statistics of pleuritis had been such as to raise expectations which were not realised. It was to be hoped that the publication of the facts would be useful, and would lead to an improvement in the prognosis and mortality of empyema. The patient exhibited by Dr. Ewald was a man, aged twenty-six, whose youth had been weak and sickly, who in 1868 and 1872 passed through attacks of pneumonia of the left side, and on November 6, 1875, had all the symptoms of pleuro-pneumonia of that side. There was very soon an abundant exudation with much displacement of the heart. After the cessation of the continued fever on the 20th, hectic set in; and on the 27th, when an exploratory puncture was made, the effusion was found to be purulent. On December 2, an incision was made under Lister's method, and a remarkable quantity of purulent fluid was removed. The pleural cavity was daily syringed out, the precaution being taken of keeping all the instruments, compresses, etc., in a solution of carbolic acid, and of always performing the act of syringing itself under the carbolic-acid spray. When the patient was shown, there was only a small opening about $3\frac{1}{2}$ centimetres (1.36 inches) long, from which only a few drops of pus escaped daily. The contraction of the chest, which was considerable, was being treated with orthopaedic exercises. On the eighteenth day after this, the patient was discharged cured, with the exception of some affection of the right apex, which had been present some time.

Apparatus for the Microscopic Examination of Air.—Dr. D. Müller described an apparatus, in which air was drawn through a small quantity of distilled water that had been examined microscopically and then boiled for a short time.

February 28. *Dyspeptic Asthma.*—Herr Henoch described four cases in which severe dyspnoea occurred as a result of irritation of the alimentary canal. The first case was that of a child, aged nine months, recently weaned; it was generally constipated, but otherwise well, until March 21, when it was taken with repeated vomiting. On the following day the respiration was hurried, and though the bowels were opened by a purge and the vomiting shortly ceased, the child's condition became hourly worse; anxiety of countenance, rapid respiration, frequent pulse, pallor of the skin, lividity of lips, and complete apathy, were the symptoms observed, while repeated examinations failed to find anything wrong with either heart or lungs. In spite of treatment,

collapse and cyanosis increased, and death was imminent, when the application of dry cupping to the thorax brought relief. Examination on the following day again revealed nothing but an apparent tenderness of the gastric region, and Traube inclined to the following explanation of the symptoms, supporting himself by the experiments of Mayer and Pribram (*Sitzungsber. der Wiener Akad. der Wiss.*, July, 1872). Irritation of the stomach led to vasomotor spasm of the small arteries, and hence successively the cold extremities, the imperceptible pulse, stagnation in the venous system and the right heart, cyanosis, accumulation of carbonic acid in the blood, and the resulting dyspnoea. It is to be observed that the child cut an incisor tooth immediately after the subsidence of the symptoms. The second case was, however, more decided in its origin. A child was brought with severe dyspnoea, the respirations being seventy in the minute, and the expiration accompanied by a groaning noise. The heart and lungs were found healthy, but the child complained of headache and tenderness over the stomach. It had been well till the preceding evening, then had pain in the abdomen, was restless at night, and was seized with dyspnoea and cyanosis in the morning. It was ordered small doses of morphia, but shortly after returning home vomited a quantity of food, amongst which were large pieces of undigested egg. This had been eaten the previous evening, and on its rejection by the stomach the dyspnoea ceased. In a third case, that of a child three months old, dyspnoea occurred suddenly after three days' constipation, and was relieved by a purge; while in a fourth patient, similar asthmatic symptoms followed upon six days' epigastric pain and distension, and were removed by an emetic.—Dr. Retslag said that some years ago he was called in haste to a patient, whom he found suffering from severe dyspnoea and moderate cyanosis. The respiratory organs were quite healthy, but the man had a sense of weight and pain at the stomach. He was a musician in a military band, and, while heated during parade, had heartily drank a glass of beer and eaten a cake. An emetic at once relieved him of all his symptoms.—Dr. Wiss had often seen, in Baltimore, cases of severe dyspnoea and cyanosis with perfect soundness of the respiratory organs. Small doses of carbonate of potash were always followed by the best result. As an illustration of results which might arise from irritation of the stomach, he referred to a case of severe eclampsia in a primipara, which had its source in obstinate constipation.—Herr B. Fränkel said that the term 'dyspeptic asthma' denoted a nervous bronchial asthma, a reflex result of irritation of the digestive organs. From this, that described by Herr Henoch differed in several essential particulars. For, in his cases, there were none of the ordinary clinical symptoms of what was commonly understood as nervous asthma. He was not satisfied with the ordinary explanations of this condition. He could imagine that contraction of the systemic arteries might give rise to hyperæmia of the lungs, like the fluxionary hyperæmia sometimes observed when the body has been cooled. As regarded the frequency of the disease, he had never seen such a case, although he had seen a number of cases of asthma. In these, there was distinct meteorism; the pressure upwards of the diaphragm would be detected by percussion; but these cases differed from those of Herr Henoch, in which there was no meteorism.—Herr Senator

remarked that the experiments of Mayer and Pribram could not well be adduced in explanation of the form of disease described by Herr Henoch. These observers found that irritation of the stomach was attended with lessening of the frequency of the pulse and rise of the arterial pressure. Herr Henoch, on the other hand, had mentioned an extraordinary acceleration of the pulse as occurring in his cases; and, as regarded the blood-pressure, Dr. Senator believed that it was not increased, but diminished; and this idea seemed favoured by the presence of cyanosis, which might well depend on an abnormal accumulation of blood in the veins, not usually consistent with increased arterial pressure. Nor could the symptoms be explained by accumulation of carbonic acid, for the dyspnoea caused by this was a dyspnoea in the physiological sense of the word, the breathing being not only quickened but abnormally deep, naturally when the respiratory muscles and especially the diaphragm were not paralysed or otherwise impeded in their action. In Herr Henoch's cases, the breathing, though accelerated, was very shallow.—Herr Henoch said that in the bronchopneumonia of children, where there were the most distinct signs of carbonic-acid poisoning—cyanosis and loss of consciousness—without material changes in the brain, there was no question of abnormally deep respiration.—Herr Senator said that it was quite true that patients who died in a state of cyanosis with pneumonia, pleurisy, etc., did not always have dyspnoeal respiration. But here the complete distension of the lungs was mechanically impeded by infiltration or compression, and the nerve-centres, which had been irritated by the carbonic acid, lost more or less of their irritability in the agony of death or in the condition preceding it.—Herr Lewin must seek for another explanation. In its central as well as in its peripheral course, the vagus nerve was connected with so many important organs, that reflex phenomena should come under observation frequently in cases of indigestion, ulcer of the stomach, gastric fistula, etc. In all the cases adduced, however, there was meteorism, and in one foetus of the breath; and hence one might assume the evidence of poisoning by the absorption of the carburetted and sulphuretted hydrogen, formed during perverted digestion, which were capable of producing dyspnoea and even asphyxia. With the discharge of these gases, the symptoms disappeared.—Herr Guttman had not unfrequently observed in adults attacks of dyspnoea, the respiratory and circulatory apparatus being quite healthy; in these cases there were no grounds for assuming the existence of bronchial asthma. It might well be assumed that these asthmatic paroxysms were the result of irritation of the vagus nerve.—Herr Baginsky thought the name dyspeptic asthma of doubtful propriety, as bronchial or nervous asthma had not yet a fixed position in the nomenclature of children's diseases. The name might lead to error, as it suggested the idea of bronchial asthma. As far as he knew, the only cases of bronchial asthma were five published by Politzer, one by Guastalla, and two by Stryck. The text-books were entirely silent on the subject of asthma in children. Attacks of dyspnoea, like those described by the author, resulting from dyspepsia, or rather disturbances of digestion, appeared to him to be not so very rare; he had lately seen such a case in a feeble, badly nourished child, three months old. In the evening he found it breathing with difficulty, the respirations

being shallow. Its belly was distended, as was always the case with children fed with amylaceous food. The relief afforded by a castor-oil emulsion, which produced several yellow pulpy stools, was astonishing. The next morning the child was well. Attacks of dyspnoea also occurred in children under other circumstances, when nothing could be detected in the lungs. He had seen a case of catarrhal angina in a child a year and a-half old, with remarkably short breathing and slight cyanosis. A most careful examination detected nothing but a slight resonance in the left supra-spinous region. Ten days later, the child had lividity of the skin, coldness of the extremities, and the respiration so difficult and shallow, that death was expected every moment. The next day the child was apparently quite cheerful, only pale, and free from all impediment to respiration. These conditions alternated several times; in a few days the extremities and face began to swell, and death occurred in convulsions. The case was one of malignant scarlatina; and it was a question whether the asthmatic—or rather the dyspnoeic—symptoms were not the result of uræmic poisoning.—Herr B. Fränkel was aware of the existence of such cases as those described by Herr Guttman. He thought, however, that the sudden and transient attacks of asthma, which were to be regarded as reflected from a fixed locality, were not to be explained in this way.—Herr Senator had noticed the possibility of poisoning by the results of abnormal digestion. But in his case, the poison (sulphuretted hydrogen) was detected in the gas which escaped from the stomach and in the urine. He did not, however, think it correct to apply this explanation to cases in which the presence of the poisonous gases had not been actually detected.—Herr Guttman did not think that the more severe forms of dyspnoea could be sufficiently explained by supposing that arterial spasm might produce attacks of dyspnoea through the accumulation of blood in the veins and the irritant action of this carbonised blood on the respiratory centre. There were, for instance, cases of angina pectoris in which there was distinctly marked arterial spasm, but nothing which could be called true dyspnoea.—Dr. A. Fränkel remarked that Traube had described cases of ulcer of the stomach in which symptoms on the part of the vascular system were absent, but the patients suffered from severe paroxysms of distress. Traube had explained this as an 'irradiation neuralgia' reflected from the stomach through the vagus nerve.—Further remarks were made by Dr. Ewald, Dr. Senator, Dr. B. Fränkel, Dr. Lewin, and Dr. Henoch.

ACADEMY OF MEDICINE IN PARIS.

May 23. *Dry Colic*.—Dr. Mialhe called attention to the fact that in order to induce slow lead-poisoning, termed lead-colic, a large dose of a lead compound is not necessary; the smallest dose is enough, if it be continued long enough. Thus Duchenne (of Boulogne) has recorded a case of lead-poisoning in a woman whose business it was to wrap up tea in tin-foil, and who consequently had no other contact with this metal than the palm of the hands and the pulp of the fingers. Hence it was necessary in a hygienic point of view to restrict the use of lead and its compounds as far as possible.—M. Le Roy de Méricourt replied to M. Ruzé de Lavison, who wished to retain on the list of diseases a special morbid entity under the

name of dry colics of tropical countries, and to M. Brequet, who wished to substitute the term saturnine myosalgia for that of lead-colic, in accordance with the idea that the pain of so-called lead-colic had its seat in the muscles of the abdominal walls only. M. Le Roy de Méricourt believed that the name of saturnine myosalgia very imperfectly represented the entirety of the very complex symptoms and morbid conditions produced by lead-poisoning, and faradisation, which M. Briquet considered as the special treatment for this morbid manifestation, would not have the rapidly efficacious effects attributed to it by his learned colleague. He believed, in opposition to M. Briquet's opinion, that faradisation, like the injection of morphia, would be more permanently successful if the pain were only the expression of a transient spasmodic condition, and did not result from the introduction of a poison like lead into the system. It was not, therefore, possible to establish the diagnosis between lead-colic and the colic of tropical countries on this method of treatment.—M. Le Roy de Méricourt replied to the objections which M. Rufz de Lavison had made. His colleague had reproached him with only having taken into consideration the etiology of endemic colic as observed on the sea-board and in the inland districts. M. Le Roy de Méricourt had not deserved this reproach, for, on the contrary, he had been scrupulous in relating all the cases observed, as well on land as on board ship. He recalled to mind that at the time of the Cochín China expedition in 1862, in a country which above all others united the conditions looked upon as suitable to give birth to this affection, seventy-nine cases of colic were treated on board the fleet, and fifty-three in the ambulance at Saigon. Out of these latter fifty-three patients, three only came from duties which kept them on land. On the other hand, out of 597 deaths in a body of 7,589 men, there were only two deaths from dry colic, and M. de Lenguetti, who gave these figures in an article entitled 'One Year in China,' adds: 'Cases of dry colic are not uncommon. I have had the opportunity of seeing several in the hospital at Saigon, and I am convinced, from the identity of the symptoms and the progress, that this affection (dry colic) can only be owing to lead poisoning.' The same opinion had been expressed by M. Cattano in a letter to Michel Lévy, communicated to the Academy of Medicine, and by M. Benoit de la Grandière. M. Le Roy de Méricourt pointed out that the so-called endemic neurosis of tropical countries had no place in the clinical treatises on the diseases of India, written by English medical men who had practised in the country, nor in the publications on the same subject by the Dutch surgeons, who had had experience in the East Indies. Passing on to America, it was observed that during the Mexican expedition, the transport ships attached to the army corps, in which the hygienic measures prescribed by the minister were put into operation, did not show any cases of this endemic. The same immunity had been found to exist amongst the troops serving in the tropics, and in the Arctic regions, notwithstanding that there were no countries in which all the climacteric and miasmatic conditions likely to produce spasmodic colic were found in a greater degree. M. Le Roy de Méricourt had read and re-read all the documents of Mexican pathology, and had not seen any mention of endemic colic. During twenty years of very extensive medical prac-

tice at Saint Pierre, in Martinique, M. Rufz de Lavison himself did not remember having seen more than three cases of the endemic neurosis of tropical countries. It was highly probable that these three cases should be attributed to some misunderstood lead-poisoning, as often happened, and of which remarkable examples are quoted, analogous to that communicated by M. Gubler, in his 'Treatise on Historical and Geographical Pathology,' concludes as follows. 'If all the known facts on the endemicity and epidemicity of dry colic be collected, we find that, as to its progress and invasion, at least in the most recent times, it has not shown itself in the endemic state on any point of the surface of the globe.' All the attempts made to establish the diagnosis between dry colic and lead-poisoning had completely failed, and had only ended in unsustainable subtleties. As regarded the epidemics of colic in Poitou, Normandy, Devonshire, Madrid, etc., the researches of writers had proved that they must be referred to lead-poisoning. M. Le Roy de Méricourt had stated that the tin provision-cases were frequently the cause of lead-poisoning, but only when they were used as improvised table furniture, and that then the acid liquids which had been kept in them for a longer or shorter time ended by forming soluble salts of lead on the lower alloy of the solderings. He had not seen that that took place when it was a question of alimentary substances contained in intact tin cases. M. Le Roy de Méricourt ended by saying that the fatalist doctrine of telluric miasms, so far as it related to the so-called colic of tropical countries led to nothing, whilst the doctrine of lead-poisoning was fruitful in successful results. A prophylactic treatment of certain efficaciousness sprang from it, as well as a treatment based on chemical data which was of incontestable efficacy, since it favoured the elimination of the poison accumulated in the animal economy. M. Le Roy de Méricourt maintained therefore the conclusions of his first argument.

June 6. *Placental Souffle*.—M. Bouillaud, on the occasion of a communication by M. Glénard, gave the summary of a memoir on the nature of the sounds of the placental souffle. In a general manner, he divided the vascular sounds into two principal classes, normal and abnormal. The normal sounds were but slightly marked in the arteries, if no pressure were brought to bear, when a dull double sound was perceived, the one diastolic, the other systolic, stronger than the first. This double sound appears due to the vibrations of the arterial tube at the time of dilatation and retraction. Normally the friction of the liquid against the arterial wall would not produce any sound, if there was no obstacle to the passage of the blood; but on pressing with the stethoscope, a souffle was brought on, even when the blood was normal.

ACADEMY OF SCIENCES.

Electro-motor Forces.—M. Besquerel communicated a memoir on the electro-motor forces produced at the contact of liquids separated by capillary diaphragms. The results obtained were as follows. 1. If, in an apparatus which has reached its maximum, the diaphragm be replaced by a new diaphragm of a similar kind, the electro-motor force falls to its minimum or very near to it. 2. If, in an apparatus of parchment paper, which has reached its maximum,

the liquids be replaced by fresh liquids, there is no sensible lowering of the electro-motor force. 3. In a paper parchment apparatus the electro-motor force may be lowered by rubbing the membrane briskly with a glass rod. The conclusion of the author was that the solutions or the substances they contain, should be condensed in the capillary spaces, in the same way as are the gases in porous bodies. And this fact was intimately connected with physiology, seeing that in animal and vegetable organism, all the liquids are separated by more or less capillary tissues, which should give rise to effects similar to those just described.

Thermo-Cautery.—M. N. Paquelin presented a note on a new thermo-cautery. This surgical instrument, constructed in M. Collin's manufactory, was applicable in the operations done by the help of fire. It was used in the same way as the galvanothermic cautery, and obtained its heat from the combustion of certain volatile hydrocarbons. Its construction rested on the property which platinum possesses in common with all metals of the same order, when once brought to a certain degree of heat, to immediately become incandescent on contact with a gaseous mixture of air and certain hydrocarbonated vapours, and to retain this incandescence during the whole time of contact with this mixture. The operator can at will run through the whole scale of temperatures from dull red heat to white heat, and can keep it up as long as the operation requires it, to any degree of heat required. Its action can be instantaneously moderated or accelerated; it can be extinguished or relighted.

Fermentation.—M. Pasteur maintained his theory of fermentations, and produced a pamphlet by Dr. O. Brefeld, who, after having combated this theory in concert with Traube, hastened to acknowledge that he had been mistaken.

Carbonic Acid.—A memoir by M. F. M. Raoult was intended to show the influence of carbonic acid on the respiration of animals. The conclusion arrived at was that the presence of carbonic acid in the inspired air has the effect of diminishing the quantity of carbonic acid produced, and above all that of the oxygen consumed in an hour—or, in other terms, the presence of carbonic acid in the air inspired is an obstacle to hæmatisation.

May 15. *Regeneration of Limbs.*—M. Philippeaux presented a note in which he demonstrated that the limbs of the water-salamander do not grow again when they are thoroughly extirpated. On the contrary, it suffices to leave a small portion of the scapula to see the anterior limb become completely reproduced.

REVIEWS.

On the Education and Training of the Feeble in Mind. By J. LANGDON DOWN, M.D., London, F. R. C. P. Lond., Physician to and Lecturer on Clinical Medicine at the London Hospital, Physician to the Normansfield Training Institution, etc. London: H. K. Lewis. 1876.

Dr. Langdon Down points out that, with the progress of civilisation, there has been a gradual improvement in the treatment of those who are congenitally bereft of reason to a greater or less extent; but much yet remains to be done, he says, in the direction of raising them out of their pitiable

condition. One scheme for their benefit which he advocates, is the provision of training schools by counties singly or in combination, for those idiots and imbeciles who belong to the pauper class. Such institutions might, he thinks, be obtained and organised in a manner similar to those asylums which the lunacy law has called into existence. He stipulates, however, that idiots and lunatics must be kept altogether apart in distinct establishments. Training schools for idiots of the middle classes might be secured by voluntary contributions. They already exist for the reception of those who belong to the upper ranks.

Dr. Down thinks it essential that the idiot should be removed from home, whatever the social *status* or means of its parents may be. In the cottage, the idiot interferes with productive industry, and entails upon the mother burdens and anxieties that are not unlikely to lead to the propagation of other enfeebled and weakly children. In the middle class family circle, it is a source of pecuniary loss, and of danger and moral contamination to its brothers and sisters. In the houses of the wealthy it is, by the very conditions of life, relegated to a solitary existence and the care of servants. In no private house can the idiot obtain that combination of medical, physical, moral, and intellectual treatment, that alone is calculated to make its life more joyous, and to quicken its powers of thought. Treatment under all these different phases properly combined can only be found in a special institution, and even there it can only be successful when *unity* of origin, execution, and design is imparted to it by the controlling influence of one mind.

The medical treatment of the feeble-minded, the true basis of all treatment, should be directed to keeping the patient in the highest possible health. It often happens that, where declension of health takes place in the idiot, there is coincidentally a loss of the mental powers that had been gained. Before the incursion of fatal disease, there is often a premonitory failure of cerebral activity. Temperature has a powerful effect over idiots, and those of the Mongolian type lose a large amount of intellectual activity in the winter, and go through a period of hybernation. Morbid anatomy teaches that, independently of defects in the cerebral mass and in symmetry of the central ganglia, there is, in the idiot, very generally defective nourishment of the vesicular neurine. A liberal, varied, easily masticated dietary should therefore be given—a dietary containing a fair proportion of nitrogenous elements, and rich in phosphates and oleaginous constituents. The sleeping apartments should be lofty, well ventilated, well warmed; and frequent ablutions must be insisted on, as the exhalation from the skin of imbeciles is something *sui generis*.

In physical training the attenuated muscles have to be called into exercise, and movements of gradually increasing complexity have to be taught. In all imbeciles there is a striking want of muscular co-ordination. Every muscle and group of muscles must be trained until the various acts of prehension, locomotion, and mastication, are more effectually performed, until the tongue becomes a willing agent, and the lips no longer permit the saliva to dribble away. This muscular education reacts upon the brain and improves its powers.

The moral education of the imbecile consists chiefly in the subordination of the will, but corporal punishment is never to be resorted to. The tact of

the teacher is shown in devising rewards and punishments to suit each special case. The withdrawal of the teacher's love should be felt as the greatest punishment, and its manifestation as the greatest reward.

The intellectual training to which imbeciles are submitted must be based on the cultivation of the senses. They must be taught the qualities, forms, and relations of objects by the sense of touch, colour, size, shape by sight, varieties of sounds, sapsors, and smells, by ear, palate, and nose; defects of speech must be overcome by tongue gymnastics, and the power of imitation. The uses of money, the value of commodities, and differences in bulk and weight, may be best taught by a shop, in which one patient acts as the trader and another as the customer. Workshops, gardening, and farming operations, concerts, dancing, and theatrical representations must not be overlooked as valuable auxiliaries in treatment. J. CRICHTON BROWNE, M.D.

Ueber Ohrblutgeschwulst von 'Geisteskranken (On Hæmatoma Auris in the Insane.) By CHARLES S. W. COBBOLD, M.D., second Assistant Medical Officer, Leavesden Asylum. 1876.

This essay was read as an inaugural dissertation before the medical faculty of the University of Würzburg, and deserves notice as being not only a succinct history of the course of the disease in question, but also containing some new and original facts. The chief German authorities—Gudden and Fischer—are quoted, and the experience of English alienists is adduced to prove some practical points.

A brief résumé of the contents, given chiefly in the author's own words, will be the best mode of reviewing this brochure. He notes that the thickening of the anterior wall of the tumour is due to a new development of cartilage on its inner surface, whilst some have maintained that the effusion was originally in the substance of the cartilage, forgetting that the anterior wall of the tumour is at first soft and flexible. Gudden has fallen into this error. After speaking of the bad prognosis in the 'insane ear,' he proceeds to the pathology, which is best made out when the stage of hardening has supervened. On section, one finds, instead of a single cartilage layer, two or more such, in some places thicker, in others thinner, than normal ear-cartilage, separated from each other by a mass of connective tissue, as a rule disposed irregularly, but capable of arrangement at times; and we may see two principal external cartilage-lamellæ, between which is a mass of new-formed tissue, holding small isolated plates of cartilage. The two external layers are joined at their borders and connected with the surrounding normal cartilage. Under the microscope, the cartilage is in no way different from the sound ear. The new tissue is rich in blood-vessels; and, in addition to the newly formed pieces of cartilage, we find in hæmatomata small bits of bone, developed during the shrinking process. The course of these appearances seems to be that at first effusion occurs between the ear-cartilage and its perichondrium, causing a separation of the latter from the former. When the absorption of this fluid occurs, a new cartilage-layer is developed from the inner surface of the perichondrium, thus causing two cartilage-layers, containing between them the results of the effused fluid. This substance consists chiefly, and often entirely, of yellowish-white connective fibres, and may be regarded as a

new perichondrium which attaches itself to the inner surface of the cartilage. During the separation process, the perichondrium is seldom scaled off as an entire layer, but is more or less torn, so that pieces remain in the cartilage; on the other hand, the perichondrium at times takes cartilage-layers with it, hence the irregularities found after death in the cartilage-layers. The ear-cartilage is very brittle when not covered with firm membrane so that it breaks and splits under the pressure of fluid. Up to now, a great uncertainty has prevailed as to the pieces of bone which are now and then found in othæmatomata. Most observers have taken the cartilage to be the source of them, but this is not the case. Dr. Cobbold quotes an instance showing after death a hard knot in a withered ear, in the fossa of the antihelix. On cutting into it, the cartilage was found split into two layers, separated by a connective tissue mass in which was imbedded a small piece of bone of the size of a pea, and flattened. It was true bone, with Haversian systems, and rich in blood-vessels. The Haversian systems were irregular, and the tissue was easily cut with a knife. Besides this bone-formation, there were, between the two cartilage-layers, small isolated plates of cartilage irregularly disposed in the connective tissue, and absolutely resembling ear-cartilage. None of the cells were in rows, but the bone seemed formed as it is in membrane. The author thinks that the absence of appearances of ossification in the cartilage itself, and the fact that the bone and cartilage touched each other at no point, prove that the one was not developed from the other; and he concludes that all bits of bone found in these 'insane ears' are developed in the same way, viz., from the fibrous mass which remains as the result of the effused fluid.

As to the causes generally assigned, viz., according to some authors, the spontaneous origin of the disease, whilst others consider it traumatic in origin, the truth would seem to lie between the two; for there must be present a morbid condition of the blood-vessels, and a slight force, such as washing the ears or rolling about in bed, may easily set up a mischief which would not otherwise have happened. Fischer thinks that the predisposition to othæmatoma depends on a specific dyscrasia, and has nothing especially to do with insanity. The signs of this dyscrasia are the frequent occurrence of petechiæ, boils, abscesses, sores, and hæmorrhages, spongy condition of tissues, œdema of feet, cold and pale skin, torpid bladder and rectum. In many persons who never had othæmatoma he found proofs of chronic inflammation in the ear-cartilage and its coverings, e.g., either between the cartilage and perichondrium or in the plate itself of the cartilage were cavities from one to six lines wide. The cavities are oftenest found on the front of the ear, are at times empty, but generally contain a few drops of yellowish or grey fluid. In these spaces blood is effused either from spontaneous rupture of a vessel (especially in one already suffering from defective blood and altered vessels), or the vessel may be burst from external violence. Gudden says, however, that the sole influence of the diseased condition of the blood (want of fibrin) shows itself by absence of coagulation, and that hence, under force, an effusion occurs more easily, the appearances of which are almost identical with those produced by forcibly smacking the ear of a corpse.

The whole pamphlet is so complete, and is written in so scientific a manner that we hope Dr. Cobbold

will translate it into English, for, though much scattered writing on this disorder is to be found in our literature, we are yet in need of a succinct account of it.

T. C. SHAW, M.D.

Medical History of our West African Campaigns.

By ALBERT A. GORE, M.D., Surgeon-Major.
London: Baillière, Tindall, and Cox. 1876.

Dr. Gore says, that 'nearly every attempt to wage war in Western Africa in former years was unsuccessful, as much from the neglect of the most obvious hygienic precautions as from the admitted deadly nature of the climate.' Our last war in that unhealthy region was well said to be 'a doctor's war,' and it is just because doctors were, from the proved necessity of the case, permitted to bring into play the resources of modern military hygiene, that it was, unlike the other little wars recorded by Dr. Gore, successful. If there be any members of the profession who hold with Dr. Oldham and the late Dr. Inman, that the soil of pestiferous climates, like that of Western Africa, is incapable of giving off emanations hostile to life, we commend this work to their candid perusal. Here they will see that a European regiment of ordinary strength, if left unprotected from the general insanitary conditions of the climate, will 'die out in four years.' Even the African born and bred in the West Indies suffers from the climate in a ratio far exceeding that of his race indigenous to the soil. The climate of this coast is nearly as fatal to seamen as to soldiers. During the three years and a half employed by Captain Owen in surveying the African coast, the vessels under his command lost thirty-eight officers and eighty-five per cent. of their crews, principally from malarial fevers. The diseases accountable for the heavy death-rate in Western Africa, are dysentery, diarrhoea, and the malarial fevers.

The work before us gives not only a history of the earlier and later medical events, including a detailed history of the rapid campaign under Sir Garnet Wolseley, but also a description of the climate, and a detailed account of the only hygienic conditions under which it is possible to carry on military operations on the western coast of Africa. Dr. Gore shows how much in all previous wars the effects of climate were aggravated by intemperance, an injudicious mode of life, and exposure. 'The seven great predisposing causes to disease were a high temperature, excessive moisture, chills and great alternation of heat and cold, a heavy rainfall, malarious emanations, a defective and unnutritious food supply, and indifferent water; and the rainy season was the period of the year when disease was most prevalent, and its effects most severely felt.'

It is obvious from Dr. Gore's narrative, as well as from the admirable account of the Ashantee campaign by Sir Anthony Home, K.C.B., principal medical officer of the expedition, and his successor in that important post, that the striking success which attended this expedition and the small mortality that attended it, were due to the manner in which the medical officers met and combated the enormous difficulties in the way of carrying on war in such a climate. And not the least part of the credit justly due to the able commander of the expedition, was the support given to the scientific officers who were his advisers on all questions relating to the health of the force under his command. It was by attention to season, food, dress, temperance, water-supply, and carriage—in a

word, all that is understood by the term 'military hygiene'—that the end was attained at the smallest possible amount of suffering. Our former 'little wars' on the West Coast of Africa were carried on on the principle that the business of doctors was to cure disease; here they were allowed to prevent it.

Striking testimony is borne by Dr. Gore to the good service rendered by the *Victor Emmanuel* hospital ship, fitted up as that vessel was in the most perfect manner for the reception of the sick and wounded, with all modern appliances for the relief of human suffering. The result obtained was that the *Victor Emmanuel*, although, on her departure from the coast, 'filled with cases of the most serious description, delivered the greater number of her patients convalescent, and in a state to return to duty.'

One of the most interesting chapters in the book is the one in which the author discusses the question of a 'spirit ration' for troops serving in such a climate as that of West Africa. His conclusions will not, we fear, find acceptance with the advocates of total abstinence in all climates and under all circumstances. Dr. Gore is, as a matter of course, opposed to everything in the shape of intemperance and the unregulated use of alcohol; but he appears to be of opinion that a moderate allowance of it in such a climate when the march is over, and when taken with food, is perhaps beneficial, certainly not hurtful, and is very grateful to the tired recipients. In this he is borne out by the opinion of some of the most careful medical observers on the expedition. He considers the use of alcohol on the march decidedly injurious and unnecessary. He sums up in the following words. That it (alcohol) 'can be dispensed with in Africa by men of hardy frame, and indomitable perseverance under great exertion, has been proved by more than one great traveller; but that it does any harm when taken in moderation at proper times and places, I do not believe.' Dr. Gore discusses the question with a full knowledge of the late Dr. Parke's experiments, and of the limits shown by that physician to be those that do not cause undue disturbance either of the nervous or circulatory systems. On one point Dr. Gore expresses himself decidedly, and that is on the good effects of alcohol in the treatment of exhausting malarial affections, 'from which the patient would in many instances not rally without it.' In this, his experience agrees with that of Sir Samuel Baker, and of some of the most intelligent companions of Livingstone.

W. C. MACLEAN, M.D.

A Handbook of the Theory and Practice of Medicine.

By FREDERICK T. ROBERTS, M.D., B.Sc., M.R.C.P., Fellow of University College, Assistant Physician and Assistant Teacher of Clinical Medicine at University College Hospital, Assistant Physician to Brompton Hospital for Consumption and Diseases of the Chest, etc. Second edition, pp. 815. London: H. K. Lewis. 1876.

Est modus in rebus. There is a fashion in textbooks as well as in other things. Take anatomy for example. Time was when the 'Dublin Dissector' and 'Quain's Anatomy' were in everybody's hands. Then Wilson's 'Anatomist's Vade Mecum,' and after that, Ellis's 'Demonstrations of Anatomy' were all the rage. Now, Mr. Heath's 'Practical Anatomy' is, we understand, a great favourite, and we are glad to see our old friends Quain and Sharpey, and

Wilson's 'Vade Mecum' coming out again in all the glory of new editions with new editors. It is the same with works on the Practice of Medicine. Hooper's 'Vade Mecum' in the hands of various editors was long, and still is, a popular book. But for awhile, as far as medical students were concerned, no books had such a sale as the manuals of Dr. Tanner. His small book (long out of print) was a marvel of concentration, and even now second-hand copies of it fetch more than their original price. Studious men may sneer at the desire for small and handy books on the part of those less fond of reading; but even the most bigoted of opponents must admit that merit is not always in proportion to size. This is well exemplified in the volume before us. In the compass of little more than 800 pages, Dr. Roberts has condensed a mass of matter on those diseases which are generally called medical in opposition to surgical, such as we think no book of the same size ever before contained: and, although thus condensed, the book is still a readable one. We hear that it is fast replacing the volumes of Niemeyer, which were until lately in fashion with students reading for medical examinations. Right glad are we to find that this is the case, for although Niemeyer's work was strong as regards pathology, it was lamentably weak in its therapeutics. There was, moreover, a sketchiness and pretentiousness about it which were far from agreeable.

The volume before us is singularly free from these faults. So far as its compass allows, it is a very thorough-going book. The question of treatment is fairly discussed as each ailment in our medical nosology comes before us, and the treatment is generally that of the best men of the day. Without wishing its author to revert to the practice of Thomas's now antiquated manual (by no means a bad book in its day) and give formulæ at the foot of every page, we cannot but think that a few more directions as to doses would increase the value of the advice given as to treatment. To give quinine in one-grain doses in order to reduce temperature in fever is simply to waste an expensive medicine, without benefiting our patients; and although general directions are given on this subject at page 77, the doses are not mentioned again under the special diseases.

Like all monographs, the work is somewhat unequal in parts. Fevers, acute diseases, and the special pathology and symptomatology of thoracic diseases (those of the heart and lungs) are given at considerable length, and better perhaps than in any other manual of medicine. But the sections on nervous diseases (though containing much valuable matter) are by no means equal to the other parts of the work; and the final chapter on skin-diseases is, we think, the worst done part of any. And this is to be regretted, because skin-diseases are of extreme value in training students to habits of accurate observation. They are also valuable as exhibiting visible examples of the same processes of inflammation and repair, which take place in internal organs where, unfortunately, they are out of sight.

The table of contents at the beginning of the book has no references to pages, and is, therefore, useless, and some signs of haste are manifest in the numbering of chapters and elsewhere. The rough way of using Pettenkofer's test given at page 583 can lead to nothing but error. Moore's test for sugar in urine (boiling with liquor potassæ) is condemned,

because liquor potassæ impregnated with lead would give a dark colour with albuminous urine; but the student is not cautioned against the common mistake of testing for sugar without first getting rid of albumen, or at least ascertaining its absence. The author gives minute directions for Fehling's test-solution, which keeps (as he admits) very badly, whilst Dr. Pavy's formula, which is much more durable and permanent, is not mentioned. Surely Dr. Roberts does not seriously mean that a registering clinical thermometer is to be warmed before use till the mercury reaches 98° Fahrenheit; for in this way sub-normal temperatures, which occur even in fevers, where temperature runs high, must escape recognition. He probably wrote 93° or 95°, and the last figure has been mistaken by the compositor, and escaped notice in revision.

The value of the book would be enormously enhanced by a few good and well chosen illustrations; and we trust that future editions will contain these. At present there are only a couple or so on the sphygmograph.

If we have thus pointed out a few small blemishes, it is because we like the book much. It is not only well printed, and neatly got up, but it is well written; and Dr. Roberts may fairly be congratulated on having produced the best text-book of medicine we possess, for the student to use not only in getting up for examinations, but as a ward-manual also. It is a book of reference, portable enough for the knapsack of the army-surgeon and the traveller. We will go further, and say that the busy consultant or practitioner may often turn to its pages with advantage. The book is one that shows its author not only to have read much, but to have well digested what he has read. It is difficult to select passages from a work of this kind, so as to convey a fair idea of the author's style, and of the way in which he has done his work, but the following on tubercle is, perhaps, an average example of both contents and style. It is from page 253.

'Anatomical Characters.—The typical form of true tubercle almost universally recognised at the present day consists of certain minute bodies termed *grey granulations* or *miliary tubercles*. These appear as small nodules or granulations, about the size of a mustard or millet seed, generally roundish, but sometimes slightly angular, well defined, firm, of a greyish-white or pearly grey colour, more or less translucent, and non-vascular. These may be quite separate and distinct, or collected into irregular groups, their individual outline being then rendered indistinct. In some structures, however, tubercle is more diffused, and appears as a greyish *infiltration*, which presents a smooth and dense section; but many so-called tubercular infiltrations are probably inflammatory in their origin. In its earliest stage tubercle is not visible to the naked eye, and it is by continued growth and agglomeration of fresh tubercles, that it becomes perceptible, appearing either as granulations or infiltrations according to their mode of arrangement.

'What has been described as yellow tubercle is nothing but nodules or masses of caseous matter, derived either from tubercle, or from various inflammatory and other morbid materials which have undergone cheesy degeneration. True tubercle may be mixed with this material; while it also tends to excite inflammation around, and thus its physical characters may be more or less modified.

'Microscopic Structure.—Tubercle may be de-

scribed as consisting of the following histological elements: 1. Lymphoid corpuscles, which are very small, round, colourless, translucent, and slightly granular, each containing a single nucleus: 2. Epithelioid cells, of larger size, very delicate, and hence liable to rupture and set their nuclei free: 3. A giant-cell, which consists of a mass of finely granular protoplasm of very varied form, often presenting processes at its margin, and having imbedded in it a great number of nuclei, chiefly at its periphery, and sometimes regularly arranged: 4. Free nuclei: 5. An intercellular substance which may be either amorphous, homogeneous, and hyaline; granular; or in the form of a fine reticulum or network of delicate fibres. There is much difference of opinion among observers as to the presence, arrangement, and relative proportion of these elements. The lymphoid cells are generally considered to be most abundant, but Schüppel describes tubercle as being made up chiefly of epithelioid elements surrounding the giant-cell. This giant-cell has attracted much attention of late years. It occupies the centre of each tubercle, and great importance was attributed to it by Schüppel and others, but Friedländer has since shown that it is found in many healthy and morbid products as well as in tubercle. Tubercle has been described by some writers as cellular and fibrous, according to the proportion of cells and fibrous reticulum entering into its formation. Friedländer, however, insists that in recent tubercle no fibres are visible, and that the appearance is due to the hardening processes employed in its preparation for microscopic examination. Tubercle does not contain any vessels or lymphatics of its own, but it may involve those belonging to the original tissue, and also pigmentary matters. As tubercle undergoes degenerative changes, its microscopic appearance alter materially.

Dr. Roberts then devotes about a page to its terminations and changes, and the tissues and organs affected, and a couple more to its pathology. Sufficient, has, however, been quoted to show the general style of the work.

Cholera Epidemics in East Africa. By JAMES CHRISTIE, A.M., M.D. London: Macmillan and Co. 1876.

The object of this work is to give an account of the several diffusions of cholera in East Africa from 1821 to 1872, with an outline of the geography, ethnology, and trade connections of the regions through which the epidemics passed.

We have risen from a careful perusal of this book with a strong conviction that, if evidence were wanting to establish the fact that cholera 'seeks man out wherever he congregates,' and that man carries it 'from congregation to congregation,' such evidence would be found in this volume. Dr. Christie remarks that, as the natives of Africa do not travel far beyond the boundaries of their own territories, the great highways are traversed only by traders at definite seasons of the year, and this uniformity of life is broken only by wars and raids of marauders in quest of slaves and cattle. The track of an epidemic of cholera can, therefore, be easily traced, and its laws of propagation more readily ascertained, than in more civilised countries, where there is an intricate net-work of lines of communication.

The author in his first chapter gives in much

detail the meteorology and climatology of Zanzibar, and in another part of his work a description of the sanitary condition of the town and island, and of the manners and customs of the population. It seems established that, notwithstanding the extremely unfavourable nature of the climate of Zanzibar, and that of the east coast of Africa generally, no epidemic of cholera ever originated there, according to Dr. Christie; the evidence he has collected goes to establish the fact that the disease has always been traced to Arabia, to the Gulf of Aden, or the Red Sea ports, with which Zanzibar at certain seasons is in commercial communication. The description given of the sanitary condition of Zanzibar and of the habits of its varied inhabitants is simply frightful; and although they seem insufficient to breed the disease *de novo*, they do in a very remarkable manner illustrate its local propagation. In spite of many ingenious and persevering efforts to explain away the spread of cholera in India by the movements of pilgrims, bodies of troops, and even of one or more persons from an infected locality, and to attribute the carrying of the disease not to persons, to man, his clothing, his personal effects, but to the disease-carrying power of air-currents, the evidence on this point is irresistible, and is strongly confirmed, as we have said, by the facts established by Dr. Christie's researches; for if we follow the traces of the epidemics whose course has been so perseveringly tracked by our author, the connection of outbreaks in Africa with outbreaks in Arabia becomes apparent, and that the main agents in the dissemination of the disease are the Mecca pilgrims. Accordingly, Dr. Christie devotes a chapter to the Moslem pilgrimage to Mecca, considered in relation to diffusions of epidemic cholera.

'The Kaabah within the Bait Ullah at Mecca is the central converging point of the Moslem world; and to and from it there is ever on the road a continuous stream of pilgrims from the remotest parts of the globe. . . . Pilgrims come from the Cape of Good Hope and Mauritius, by way of India, in square rigged vessels, and from Madagascar and the islands of the Mozambique Channel by way of Makulla or Aden, in native craft. Zanzibar and its maritime dependencies, from Cape Delgado to Guardafui, sends its contingent during the south-west monsoon, by Makulla or Aden, and in some cases to Hadeida or Lidda direct.'

In describing the 'pilgrim ship,' the marches and sufferings of the different caravans, all converging on Mecca, the fatigues of the journey, and deaths, as well as the duties and ceremonies performed by the pilgrims on arrival, Dr. Christie draws largely on the narrative of Captain Burton, who, it is well known, made the pilgrimage in the guise of a Moslem pilgrim. Nothing can be more disgusting than the accounts quoted from Burton, Burckhart, Potts, and other Europeans of the sanitary condition of Mecca; and although our author is of opinion that there is no proof that cholera can be traced merely to such unsanitary causes as prevail both at Mecca and Zanzibar, there can be no doubt of the effect of the fæcal atmosphere, the decomposing blood of the victims slaughtered in the valley of Mina, the severe fatigue endured by all the pilgrims, the drinking without stint of the purgative waters of the otherwise impure well of Zem-Zem within the temple of Mecca, the arbitrary change of dress which is imperative on all without exception of country, age, constitution, or season of the year. 'No matter what the season of

the year may be, genjal spring, the burning heat and simoom of summer and autumn, or during the rain and tornadoes of winter,' the obligation to assume the thrâm or sacred habit is binding on all. It consists only of two woollen wrappers, one 'to cover their privities,' the other to be thrown over the shoulders, leaving the head bare. Add to the above the frenzied excitement of the pilgrims, the effect on health of the crowding together an immense concourse of people within a very limited space at Mecca, Arafat, or Mina, and within the Kaabah and the mosque, where even the diseased and the dying struggle to join the throng, 'that they may die in the performance of the religious ceremonies.' 'Not only,' adds Dr. Christie, 'are the dying commingled with the living; even the dead are introduced into their midst, and we have a combination of circumstances well adapted to act as predisposing causes and means of propagation of cholera, and for regarding Mecca, during the pilgrimage season, as one of the most favourable spots for the germination or reproduction of an epidemic.' With such facts before us we cannot wonder that every caravan route from Mecca has been at some time or other a cholera track, and that wherever the pilgrims have reached, on their journey homewards, centres of population, the disease has spread amongst the people. The work is illustrated by an instructive map, showing the geographical distribution of cholera in Eastern Africa in 1864-1871.

The labours of Dr. Christie form a valuable contribution to our knowledge of the spread and propagation of cholera. We have said that his researches establish the fact that cholera is not endemic in East Africa, and that it invades that country invariably from Arabia, the Gulf of Aden, or the Red Sea ports; and it seems equally clear that, although Arabia is often scourged by it, the disease is not endemic there, but reaches that country from India, and that what gives rise to the notion that cholera is endemic in some of the provinces of Arabia, is the fact that, from the causes stated above, one invasion of the disease succeeds another with such rapidity as to give it an appearance of being endemic.

NEW INVENTION.

SALICYLIC SOAP.

Salicylic acid is gradually becoming better known as an antiseptic. So long as it was attempted to use it merely as salicylate of soda or salicylate of potash, so long were the antiseptic properties of this elegant compound neutralised and rendered dormant, until the salt so formed was again split up by the combination of a stronger acid with the bases. Salicylic acid in solution has been for some time admitted to be of the greatest value as preventing putrefactive decomposition in diseased but living tissues.

In the form of solution, however, it cannot be combined with an alkaline soap so as to preserve its antiseptic powers. This has been one of the main hindrances to the use of this acid in domestic treatment of all the numerous minor affections of the skin, and particularly of those which arise from the irritability caused by heat and other influences of summer weather.

Equally valuable with carbolic acid in all cases where it is advisable to use an antiseptic without consulting special medical advice, it is superior to

carbolic acid in all systematic treatment of tender skins or those which require a gentle alleviation of the tendency which produces roughness or dryness from wind or sea air, or slight irritability and blistering during hot weather.

More particularly, its emollient and antiseptic properties are invaluable when the perspiration becomes disagreeable.

Messrs. Tidman and Son have been fortunate in obtaining a formula, by which the antiseptic power of salicylic acid is so combined with other agents in the preparation of their salicylic soap, that its intrinsic properties, so far from being diminished in the process of soap-making, are largely augmented.

The most delicate skins find relief from the constant use of this soap, and slight skin-affections are generally favourably influenced; while the perfume which is added gives a refreshing scent, it conveys a lasting and agreeable tonic to the skin.

This soap has one other merit, that it can be used pleasantly, and will make an efficient lather with harder water than any other absolutely free from marine soap.

RECENT GERMAN BOOKS.

Published by P. Enke, Stuttgart.

Atlas der Frauen-Krankheiten von Dr. Hermann Beigel. 288 Tafeln in Holzschnitt. Lexicon-Octav. geheftet. Preis: 14 Mark.

Ueber die hauptsächlichsten Vorgänge und Bedingungen, unter denen die Heilung der Lungenschwindsucht zu Stande kommt. Von Dr. Dührssen. 52 Seiten in Octav. Preis: 1 Mark, 20 Pfg.

Grundzüge der Arzneimittellehre. Von Dr. K. F. H. Marx. 82 Seiten. 8. Preis: 1 Mark, 60 Pfg.

Die Bäder, Quellen, und Curorte Europa's. Von Dr. J. Hirschfeld, und Dr. Wilh. Pichler. II. Band. 8gr. Preis: 14 Mark. Preis des complete 1,200 Seiten umfassenden Werkes, 26 Mark.

Grundriss der Pathologie und Therapie der Syphilis und der mit dieser verwandten venerischen Krankheiten. Von Dr. Hermann Zeissl. 8gr. 348 Seiten. Preis: 8 Mark.

Published by August Hirschwald, Berlin.

Das Princip des Wachstums. Eine anatomische Untersuchung von Prof. Dr. Fr. Boll. 1876. 8gr. Mit 1 Kupfertafel und 3 Holzschnitten. Preis: 3 Mark.

Compendium der pathologisch-anatomischen Diagnostik nebst Anleitung zur Ausführung von Obductionen von Dr. Johannes Orth. 1876. 8gr. Preis: 10 Mark.

Die Physiologie der Haut experimentell und kritisch bearbeitet von Dr. A. Roehrig. 1876. 8gr. Preis: 5 Mark.

Handbuch der speciellen Augenheilkunde. Von Dr. C. Schweigger, Professor und dirig. Arzt der Abtheilg. für Augenranke der königl. Charité zu Berlin. Dritte Auflage. Mit 47 Holzschnitten. Preis: 12 Mark.

Verhandlungen der Deutschen Gesellschaft für Chirurgie. Vierter Congress. (Berlin, 7-10 April, 1875.) 1876. 8gr. Mit 9 Tafeln und Holzschnitten. 14 Mark.

Der Diabetes mellitus. Auf Grundlage zahlreicher Beobachtungen dargestellt von Prof. Dr. J. Seegen. Zweite vermehrte Auflage. 1875. 8gr. Preis: 8 Mark.

Handbuch der pathologischen Anatomie von Prof. Dr. E. Klebs. Fünfte Lieferung. Mit 25 Holzschnitten. 8gr. Preis: 8 Mark.

Published by G. Reimer, Berlin.

Handbuch der allgemeinen und speciellen Balneotherapie. Redigirt von Hofrath Dr. Th. Valentiner. Zweite Auflage. Preis: 13 Mark.

Lehrbuch der Chirurgie und Operationslehre, besonders für das Bedürfniss der Studierenden bearbeitet von Dr. Adolf Bardeleben. Siebente Auflage. Vierter Band. Preis: 11 Mark. Bd. I-IV. complet 44 Mark.

Klimatische Winterkurorte. Ein Leitfaden für Aerzte und Laien von Dr. H. Reimer, königl. Sanitätsrath. Zweite neu bearbeitete und stark vermehrte Auflage. Mit einer Uebersichtskarte und 3 Plänen. Preis: 5 Mark.

Pyrmont für Kurgäste geschildert von Hofrath Dr. Th. Valentin, Arzt daselbst. Dritte vielfach veränderte Auflage. Preis: 1 Mark 60 Pf.

Untersuchungen über die Vegetationsformen von *Coccobacteria septica*, und den Antheil welchen sie an der Entstehung und Verbreitung der accidentellen Wundkrankheiten haben. Versuch einer wissenschaftlichen Kritik der verschiedenen Methoden antiseptischer Wundbehandlung. Von Dr. Theodor Billroth. Mit fünf Kupfertafeln und einem Holzschnitt. Roy. 4°. 244 u. XIV Seiten. Cartonirt. Preis: 48 Mark.

Ueber die Behandlung der constitutionellen Syphilis und der Quecksilberkrankheit an den Schwefelquellen, vorzugsweise in Aachen. Von Geh. Sanitätsrath Dr. Alexander Reumont. Preis: 75 Pf.

MISCELLANY.

M. POTAIN has accepted the share of the joint editorship of the *Bulletin Général de Thérapeutique*, vacant through the death of M. Béhier.

Le *Journal des Sages Femmes* contains an article on the 'Rights and Duties of Midwives,' in which the writer points out that the midwife should take care that no syphilitic child is allowed to be suckled by a healthy wet-nurse.

CHARTREUSE.—Dr. Decaisne lately read a paper at the Academy of Medicine on the liqueurs known as Chartreuse and Eau de Mélisse de Carmes, in which he pointed out that the plants used in manufacturing this liqueur are the same as those used for absinthe, namely, angelica, coriander, aniseed, hyssop, balm, peppermint, thyme, rosemary, sage, sweet marjoram, arnica, absinthe, rosemary, *calamus aromaticus*, cinnamon, cardamoms, mace, nutmeg, cloves, balsam, and Tonquin bean. These plants are all classed as excitants in therapeutics, and show the same physiological effects. They contain all, or nearly all, the more or less active and more or less dangerous essential oils. Their proportion in the fabrication of the three liqueurs varies according to the liqueur and to the flavour which the distiller wishes to impart to it. In equal, or nearly equal doses, the effects of absinthe, of Chartreuse, and of Eau de Mélisse, are identical on the animal economy, and especially on the nervous system, and produces alcoholism in the same manner. *A priori*, and this conclusion can be demonstrated by ulterior reasons, M. Decaisne is of opinion that all the liqueurs made from the same or similar plants containing active essential oils, and showing the same or about the same alcoholic percentage, may, when they are too freely used, produce the same accidents which constitute the condition known as alcoholism.

THE WOMEN'S PAVILION AT THE PHILADELPHIA EXHIBITION contains a large glass case labelled 'Materia Medica' from the Women's Medical College of Pennsylvania—the first of its kind—and at which, though it is very young, some sixty or seventy 'lady-doctors' of the future are already qualifying for their degree. Elsewhere in the building are artificial teeth made by the only woman-dentist in Philadelphia and regularly graduated in the 'Dental College.' Two Philadelphian lady physicians also exhibit electro-magnetic appliances for the human body.

THE MARRIAGE OF NEAR KIN.—M. Saint Martin, of Madrid, has published some statistics which tend to prove that consanguineous marriages have but a very slight influence in producing the ill effects which are generally ascribed to them. The results of his figures are as follow:—Out of 161 consanguineous marriages 12 were childless. The remaining 149 unions had produced 551 children, out of which 300 were in good health, 236 were dead, and 15 sickly. The latter showed the following affections:—5 deaf and dumb, 2 idiots, 6 scrofulous, rachitic, or tuberculous, and 2 hemiplegic.

A NEW ARTIFICIAL EYE.—Among the curious developments of science is the recent production, by Dr. C. W. Siemens, of an artificial eye sensitive to light. The new eye is composed of an ordinary glass lens, backed by an artificial lens of selenium. Mr. May, a telegraph clerk employed at the Valencia station of the Atlantic cable line, first observed in 1873 that the electrical resistance of selenium was instantly altered by light, the resistance being diminished by increase of light. Dr. Siemens made use of this peculiarity of selenium in the construction of his novel eye. An electrical circuit is arranged, of which a bit of selenium forms a part, and constitutes the retina. When a strong light is admitted into the lens and falls upon the selenium retina, the current of electricity flows and (by acting upon small magnets) may be made to work the artificial lids of the eye, opening or closing them according to the intensity of the light.

THE REACTION-TIME.—The time elapsing between the action of an external stimulus on some part of the body, and the giving of a signal (previously agreed upon) in reply, has been determined in the case of several senses, by various experiments. A short time ago MM. Vintschgau and Hönigsmied sought to determine this 'reaction-time' for sensations of taste on the point of the tongue; and in the subject experimented on, this was found to be, for ordinary salt 0.1598", for sugar 0.1639", for acid 0.1676", and for quinine 0.2351". It is interesting to compare the results which the same observers have recently obtained in further experiments as to the reaction-time for sensations of touch on the tongue. This, in the same individual, was found to be 0.1507" in the case of the tongue being touched with a pencil; a smaller value, therefore, than that of the shortest interval in the former case of taste. In the middle of the tongue the reaction-time, on touching with a pencil, was 0.1527". A weak electric stimulation of the tongue-point was answered after 0.1813", whereas with a stronger electric stimulus the answer came in 0.1452". These numbers represent, in all cases, the averages of all the experiments. It will be seen, then, that the point of the tongue is most sensitive for strong electric stimuli, and the order of sensibility for the remaining stimuli, was (for this individual), contact, saltiness, sweetness, sourness, weak electric stimulation, and bitterness. Other persons on whom similar measurements were made, gave values that were different both relatively and absolutely, and the results for different persons appear to be not comparable together. Various secondary influences play an important part, among which may be cited the thickness of the mucous membrane at the particular part experimented on; this may considerably increase the reaction-time. An estimate of the comparative sensibility of the separate organ of sense can best be had from comparisons in one and the same individual.

INFLUENCE OF VACCINATION.—In the German army, vaccination and revaccination are obligatory. According to statistics collected by the German authorities, the German army, which numbered a million men during the war with France, lost only 286 men by variola, while the French army lost nearly 26,000 by that disease.

A FAMOUS SURGICAL INSTRUMENT MAKER.—M. J. F. Charrière, the noted surgical instrument maker of Paris, has lately died at the age of seventy-three. Charrière was a Swiss by birth, but came to Paris when he was twelve years of age, to be apprenticed to a cutler. Having served a five years' term, he bought for a hundred pounds the little business where he had worked, and set earnestly to work to study his occupation, bringing to bear upon it the devotion and affection of a true artist. Soon Sheffield heard of the steel instruments which Charrière was producing, and consumers placed so great a reliance on his products that surgical instruments became an acknowledged branch of Paris manufacture, and in less than twenty-five years from the date of commencing business Charrière had exchanged his little cutler's shop in the Court of St. Jean-de-Labian for large workshops in the Rue de l'École de Médecine, in which more than 400 artisans were employed. At the London Exhibition of 1851 Charrière competed boldly with the most eminent English makers, and so successfully (say the French journals) that the international jury had determined to award him the Council Medal, the highest prize they had to give, and that this was only prevented by the energetic jealousy of our own countrymen. However this may be, a theatrical scene was got up when the French honours of the exhibition were distributed in November, 1851. Louis Napoleon, then President of the Republic, was officiating, when the Baron Dupin asked permission to proclaim 'in the name of the thirty-six members of the French jury, in the name of the Institute, and in the name of the Academy of Medicine, that M. Charrière was the first artist in Europe in his own speciality.' In consequence of this speech Napoleon conferred on the old cutler's apprentice the officer's cross of the Legion of Honour. The same evening a banquet was given at the Elysée in honour of the occasion, at which Louis Napoleon presided. In the course of the evening the President stepped up to M. Charrière, and taking his own cross from his breast, said, 'Allow me the honour of exchanging decorations.' Napoleon's cross was composed of diamonds. Twenty years ago M. Charrière handed over his business to his son, who, however, died soon afterwards. The father again took his old place, but had altogether retired several years before his death. His successors are two of his pupils, Messieurs Robert and Collin. To this firm was awarded a diploma of honour (the chief prize) by the jury of the Vienna Exhibition.

ARMY HOSPITALS.—The following account of the Hospitals of the Medical Department of the United States Army, exhibited at the Centennial Exposition at Philadelphia, is condensed from the *New York Medical Record*. The Model Army Hospital, designed to represent the system of hospital construction actually employed by the medical service of the army, both in peace and war, for twenty-four beds, which has been built in the Exposition grounds, is described as a frame building, with a shingle roof, surrounded by a verandah. It consists of a central administration building, 35 feet front by 39 deep, and two stories high, with a two-storied back-building 40 by 14 feet, and two wings 45 feet by 24, one for each ward of twelve beds. The floor of the whole building is raised three feet above the ground, and is well supported on timber posts. In the plan of the ground floor are the wards, each 24 ft. by 45; dispensary, 14 ft. by 15; office, 14 ft. by 15; mess-room, 14 ft. by 20; kitchen, 14 ft. by 14; nurses' room, 14 ft. by 15; earth closets, each 9 ft. by 9; bath-room and lavatory; closets; pantry, 8 ft. by 10. In the plan of the second story is the steward's room, 14 ft. by 15; spare room, 14 ft. by 15; attendant's room, 14 ft. by 19; store-room, 14 ft. by 15; room for violent patients, 14 ft. by 20. All the walls and ceilings are lathed and plastered with

two coats, the finishing coat being plaster of Paris, and the entire woodwork usually painted is covered with two coats of paint. The wards are 15 ft. high in the clear from floor to ceiling. Ridge ventilation is provided for the summer months by means of two boxed openings in each ward, carried from the middle line of the ceiling to the ridge. These openings are ten feet apart, and are each 10 feet long by 2½ feet wide. In the winter months the opening at the ridge is to be closed, and ventilation effected in the following manner: A large stove is placed in the middle of the ward. Fresh air is introduced by an air-box 18 inches square, which passes underneath the floor of the ward from side to side, open at each extremity to the external air, and opens in the centre of the ward beneath the stove by means of a register; when a ventilating stove is used, the place of the register is occupied by a pipe, which connects the air-chamber of the stove with the air-box beneath the floor. The pipe of the stove passes up through a close-fitting collar in the ceiling. One foot above the ceiling it enters a shaft or jacket about 24 inches in diameter, which pierces the roof, and extends four feet above; it is covered with a sheet-iron cap, pierced in its turn by the stove-pipe, which is capped in the same manner. At each end of the ward, and two feet from the centre, there is an opening in the ceiling one foot square, from which an air-box passes to a box enclosing the lower mouth of the shaft surrounding the stove-pipe. The heat of the stove-pipe causes a continuous upward current in this shaft, which is supplied by the vitiated air from the ward through the air-boxes. In each of the earth-closets there is a ventilating shaft six inches square, and the gas-burner of the room is situated directly beneath it. These earth-closets in the regulation hospitals are intended for very sick patients only, accommodations for other patients and the attendants being provided in a suitable detached building. A small detached building is also intended to be provided for the purposes of a dead house; and cases of small-pox and other contagious diseases are to be treated in hospital tents. In fitting up this building for the Exhibition of 1876, the rooms are occupied as follows. On the first floor a ward, serving for the exhibition of hospital furniture, bedding, and clothing; a room for the exhibition of the models of hospitals, hospital steam vessels, hospital railway cars, ambulances, etc., and for specimens from the Army Medical Museum; while the other rooms are used for the exhibition of medicines, medical stores, and chemicals; surgical instruments, books, blanks, and the publications of the Surgeon-General's Office, mess furniture and utensils, kitchen utensils, and the private office of the surgeon in charge, and the rooms in the second story serve for the exhibition of prosthetic apparatus, litters and stretchers, medical panniers, knapsacks, etc. The five small models of hospitals on exhibition represent a barrack ward, as adopted by the War Department in the summer of 1864, and four of the great general hospitals, so-called, which attained celebrity during the war.

BIOLOGICAL INSTRUMENTS AT THE SCIENTIFIC LOAN COLLECTION.—Among the instruments employed in biological research at the Loan Collection is the original compound instrument constructed in the latter part of the sixteenth century by Zacharias Janssen. In striking contrast to its rude simplicity stand the two microscopes built by Benjamin Martin about the middle of last century; in their size, and the intricacy of their adjustments, they equal or surpass the boldest efforts of contemporary makers. The instrument employed by Lyonet in his famous investigations into the anatomy of *Cossus ligniperda* ought not to be overlooked. It resembles the ordinary dissecting-microscope in use at the present day, the lenses being attached to a small brass table by a curious succession of ball-and-socket joints admitting of universal movement. Microscopes by modern makers are largely represented. They illustrate two leading tendencies: one in the direction of mechanical simplicity; the other, towards specialisation. Instead of one instrument to serve all purposes, there are here a number of models

designed to meet the special needs of the histologist, the chemist, the mineralogist, etc. A microscope (on Ross's model), exhibited by the Geneva Association for Constructing Scientific Instruments, presents a small improvement which seems worthy of being more generally adopted: the objectives, instead of being screwed on to the tube, are kept in position by a pair of cylindrical spring pincers; this enables one power to be substituted for another with much less expenditure of time than is usually required for the purpose. The collection of accessory apparatus includes a series of moist and hot chambers, and one of microtomes. Among the former may be noticed the hot stage of Professor Vogelsang for demonstrating the effects of a rise of temperature on the bubbles of carbonic acid in quartz crystals; the source of heat is a platinum wire stretched to and fro across an annular thermometer bulb, and through which a voltaic current may be made to pass. Also the moist chamber contrived by Dallinger and Drysdale for the continuous observation of minute organisms with the highest powers without allowing the drop of liquid in which they are contained to evaporate. Prof. Klebs exhibits glass chambers in which the multiplication of *Schizomycetes* may be continuously watched. There is a great variety of instruments, some of them very complicated, for cutting thin sections of animal and vegetable structures; among them may be noticed the freezing microtome of Prof. Rutherford; a very simple freezing apparatus by Dr. Pritchard; and microtomes for objects embedded in paraffin, etc., by Krause, Hensen, Klebs, His, and others. The collection is comparatively rich in instruments employed for investigating the physiology of the circulation. Fick's spring kymograph, and several improved models of the mercurial kymograph are exhibited. The largest piece of apparatus in this department is a compound kymograph by Professor Hering of Prague, which includes two mercurial manometers, a spring manometer, chronographic signalling apparatus, and a recording drum on which several curves may be simultaneously inscribed. Vierordt's hæmatometer is of some interest historically. In the case containing M. Marey's contributions may be seen a great many of the instruments figured in his well-known treatise on the circulation: various forms of recording apparatus (combinations of tympana, pneumatic tubes, and writing levers), and the ingenious *ampoules*, by means of which the variations of pressure in the different cavities of the horse's heart may be graphically registered. Most of the sphygmographs exhibited are modifications of Marey's original instrument; among them may be noticed Stein's photosphygmograph, in which a luminous dot projected upon a moving strip of sensitive paper takes the place of the usual writing lever; Sommerbrodt's instrument, which transfers the movements of the arterial wall to a point oscillating in a vertical plane, without the intervention of a spring; Brondgeest's pansphygmograph—a revolving drum, a sphygmograph, a cardiograph, and an instrument for registering the respiratory movements, packed into a box of very moderate size. There is also a collection of sphygmoscopes and sphygmometers, among which the ingenious gas-sphygmoscope of S. Mayer deserves mention. Among the instruments for investigating the respiratory function may be noticed Riegel's double stethograph, the stethocardiograph of Dr. Sanderson, and the instruments for stethometry contrived by Dr. Ransome. Prof. Hering sends a very large machine for carrying on artificial respiration. The pumps usually employed for this purpose only drive air into the lungs, and leave expiration to be performed by the elastic reaction of the pulmonary tissues, and the resilience of the thoracic walls: in Hering's apparatus, expiration is provided for as well as inspiration; any mixture of gases may be substituted for atmospheric air; and the products of respiration may be collected for analysis. Prominent among the apparatus for studying the movements of living organisms are the ingenious contrivances devised by M. Marey for analysing the mechanism of flight in birds and insects, and that of locomotion in man and in the horse. Inquiries into the laws of muscular contrac-

tion are illustrated by a variety of myographs and myoscopes. Starting from the original muscle-balance of Prof. Schwann (1836), there are several forms of the spring myograph of Dubois-Reymond, Rosenthal's rotating myograph, several instruments by Marey, and a differential myograph by Dr. Brunton for investigating the influence of poisons on muscular contractility. Electro-physiological instruments are poorly represented by a few sets of non-polarisable electrodes and commutators. Galvanic batteries for medical use, and a complete set of Middeldorff's galvanocaustic apparatus, though interesting, appear somewhat out of place in an exhibition of this kind. Amongst the thermometric instruments are also several delicate mercurial thermometers by Geissler, Becquerel's thermo-electric needles, and the electrical thermometer of Rosenthal. For the measurement of surface temperatures no more effectual instrument has been devised than a mercurial thermometer with its bulb spirally twisted in a horizontal plane; even Dupré's modified surface-thermometer, which has its bulb roofed in by a concave reflector, is not sufficiently rapid and accurate to meet the requirements of the case. Among the apparatus for investigating the chemical processes going on in the living organism, that of Voit occupies a conspicuous position. It consists essentially of an air-tight chamber in which a small animal, such as a dog or rabbit, may be confined; in connexion with this chamber is an elaborate set of meters, and tubes filled with re-agents, which enable the gases absorbed and given off by the animal to be quantitatively determined during long periods of time. Physiological optics are abundantly illustrated. Foremost in this section come the instruments lent by Prof. Donders, of Utrecht, chiefly intended for investigating the ocular movements, the phenomena of accommodation and refraction, and their anomalies. In the same collection may be seen the neomatometer and neomatograph contrived by the illustrious Dutch physiologist for inquiries into certain psycho-physical processes. Several instruments belonging to the late lamented Von Graefe are exhibited by Dr. Weber, of Darmstadt, and possess more than a merely historical interest. Investigations into the vital phenomena of plants are illustrated by a set of incubating chambers for germination, Reineke's apparatus for measuring the velocity of growth, Cohn's apparatus for demonstrating Knight's experiment on the influence of gravity on the direction of growth in the roots and stems of budding plants. The botanist will likewise feel interested in the plan of the Institute of Vegetable Physiology in the University of Breslau, under the direction of Prof. Cohn. Founded in the year 1866, it has already contributed largely to the advance of botanical investigation; the results of the original work carried on there being published in Cohn's well-known *Beiträge zur Biologie der Pflanzen*. Most of the anatomical models contributed by German makers are decidedly inferior in quality. The Hunterian Museum lends a few specimens illustrating a greatly improved method of mounting skeletons, which enables the constituent bones to be examined on all sides without spoiling the appearance of the articulated skeleton as a whole. A number of huge flowers made of gutta-percha or *papier-mâché*, are exhibited by Brendel, of Berlin. They may be taken to pieces, and their structure demonstrated to a large audience. Three schemata of the circulation, by Donders, Hering, and Rutherford, belong to this department; the ingenious schema of M. Marey is represented only by a diagram. The collection also includes a great variety of craniometric and other apparatus employed in anthropological investigations. To practically demonstrate his process for the partial recovery of poisons after they have been administered in fatal doses, Prof. Sokoloff, of St. Petersburg, shows glass tubes containing:—1. 0.057 gramme prussic acid, of which 0.051 gramme was recovered after sixty days. 2. 0.500 gramme of coniine, of which 0.125 gramme was recovered after forty-five days. 3. 0.300 gramme of nicotine, of which 0.076 gramme was recovered after twenty days.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BROWN ON ARSENICAL PAPER-HANGINGS.

The following paper, read by Dr. Francis H. Brown, Surgeon to the Children's Hospital, Boston, before the Boston Society for Medical Observation, is published in the *Boston Medical and Surgical Journal*, May 11, 1876.

During the past year I have had occasion to give advice in a number of cases involving grave symptoms, of long and persistent continuance, and of a nature so masked as to puzzle, for a time, both friends and physicians; but which, from the history and the symptoms, joined with the surroundings which I found in each case, I believe to have been due to arsenical poisoning from wall-papers on living or sleeping-rooms, which the patients had occupied for a longer or shorter time.

It will be remembered that the pigments used by manufactures of arsenical wall-papers are composed very largely of arsenite of copper and of acetoarsenite of copper or Schweinfurth green; the former containing 50 per cent. and the latter 58 per cent. of arsenious acid, which dangerous elements are applied to the paper by size, giving but a feeble cohesion when exposed to the air or to the danger of attrition from various causes. Even the flock papers, which have been looked on as innocuous, often have a layer of arsenical pigment, which in time becomes equally dangerous.

The subject of arsenic-bearing wall-papers has been freely discussed in both home and foreign journals for the past twenty years; nowhere more fully or satisfactorily than in the Massachusetts 'State Board of Health Report' for 1872. Cases and series of cases have been given, some by physicians who have experienced the ill effects in their own persons, and all bearing a striking resemblance to those I have had under notice.

The symptoms in these cases have been of a composite character affecting the system generally, with more marked evidences of disturbance in the digestive and respiratory systems, and with a strong tendency to neuralgic and mental disorder.

In connection with these cases, I shall show specimens of paper from rooms which the patients have occupied, and a considerable number of others which have been offered for sale by manufacturers, and intended for domestic use. The former specimens offer the strongest evidence for the opinion I formed of the disturbing element.

The series of symptoms is very well described in their usual sequence by a non-professional writer in the *British Medical Journal* for July 22, 1871. Referring to a number of cases which occurred in his own family, he says, 'First appeared irritation of the mucous membrane, causing diarrhoea and vomiting, with various other symptoms of severe gastric de-

range, resulting in permanent indigestion; also incessant severe cold in the head, which in one instance lasted for several years without being touched by any remedy; ulcerated throats, with acute inflammation, resembling diphtheria and quinsy; severe spasmodic cough, spasmodic asthma, bronchitis, and congestion of the lungs; soreness of the mouth, lips, and tongue, which appeared as if scalded in patches; inflammation of the eyes and eyelids (the conjunctivæ being invariably bright red), in one case threatening absolute loss of sight; congestion and torpidity of the liver, with the various symptoms resulting therefrom; and severe bilious and feverish attacks. This was, in short, irritation of every organ. In many cases, if not in all, the action of the heart was weakened, and in some palpitation frequently occurred. There were pains in various parts of the body, especially across the shoulders, down the spine and limbs, also in the joints, which were often stiff and swollen; scaling of the skin, and irritating eruptions, which no remedy ever relieved except Turkish baths. The effects upon the nervous system were most remarkable, producing a thoroughly shattered condition; great irritability, depression, and tendency to tears, with unusual prostration of strength. . . . The list also includes giddiness, headache, acute ear-ache, and neuralgia; bleeding at the nose; frightful dreams; hysterical attacks; faintness; cramps, rigor, and numbness of the limbs; rigid spasms and convulsions. The last symptoms developed in the worst cases were loss of memory and threatenings of paralysis, also spasms, with twitchings of the body and limbs.'

CASE I. Mrs. A., a lady, fifty-six years of age, in easy circumstances in life, of a peculiarly active and nervous organisation, of regular habits of life, was exposed in her bed-chamber, for a number of years, to the influence of arsenic paper. She had been previously entirely healthy, never having had any illness other than temporary troubles of small moment. Menstruation ceased to occur within five years without any abnormal symptom, the critical period being only marked by the cessation of the monthly flow.

Twelve years ago she married, and came to live in a home near an inland city. Her chamber was on the ground floor of a large house, and had been newly hung with a paper of a light green hue. The room was occupied only at night, most of the time during the day being spent in other parts of the house, and, in the summer months, in the open air. To this circumstance, of course, is due her freedom from trouble for a considerable period.

Three or four years after occupying the room, or perhaps a little earlier, she began to have a feeling of general malaise. The first thing she recalls is a sensation of exhaustion, which she then thought due to one or two severe falls, but which is now more satisfactorily explained. Being a person of strong will, she made every endeavour to throw off or resist this sensation, but it would as constantly return. It was especially difficult for her to rise in the morning, although awake at a very early hour. The debility increased as the illness went on. She would feel quite well and strong for a time, and would at once experience the sense of prostration on making any attempt at movement, and, at times, on any unusual mental exertion, making the duties of a housekeeper particularly onerous. She speedily increased considerably in weight, from about 125 to 160 pounds;

this condition lasted for some months, and then gave place to emaciation.

At certain intervals afterward the various symptoms of the digestive, nervous, and circulatory systems, which I shall mention, appeared and increased in severity up to the time I saw her, in June, 1875. The precise date of the access of each symptom is unknown, but each had shown itself, either continuously or at intervals, for a number of years before.

I found her in bed, perfectly prostrated, hardly able to move hand or foot; with skin very dry and rough; hands and feet cold or cool to myself and to the patient. I do not recall either the pulse or the temperature, though both were duly noticed at the time. Emaciation was marked; a countenance naturally rosy had become sallow; tongue inflamed, dry, cracked, with brownish coat in centre; gums also dry and angry. The sensation of dryness was apparent to herself, with a feeling as if the mouth were lined with flannel. No sensation of dryness or pain in the throat or oesophagus. Nausea, often about ten P.M., and nearly always when she awakened, but not during the night, unless she happened to be up and about for any purpose. At times a pressure in the stomach; frequent thirst of an evening; seldom during the day; capricious appetite.

During her early years, at her home in Philadelphia, she had often had diarrhoea, but she had been free from it for some years. Two or three years ago it came on at intervals, its presence being ascribed to diet and the usual causes; of late it had become more marked, the discharges being watery and painful. She had never noticed blood. No oppression in breathing; no catarrhal trouble, cough, or other noticeable pulmonary complication. Her eyes had for some time shown signs of weakness and congestion. They had previously been very strong. At last she could not open the lids at night without lifting them with her fingers. At the time I saw her there was marked conjunctivitis, as if from some external irritation. No headache, but an 'aching, tired sensation' in base of the brain, which ran down the spine to the lumbar region. At times, during the past few years and never before, a tenderness in the neighbourhood of the liver, which would pass away after a slight diarrhoea. Her temper was never irritable or much depressed, but her household duties seemed to weigh on her, and were more than ever a responsibility. A carbuncle, or perhaps a large boil on the back, was reported as having occurred three or four years before; otherwise no eruptions, carbuncles, or furunculi. The sleep was more easily disturbed than when in health, and she had often awakened chilly or feverish. The feet and legs, to the knees, were frequently cramped, and had been relieved by warm applications and friction.

The symptoms detailed had always been, to a certain extent, relieved during absence from home; but in about ten days after her return the exhaustion and other evidences of disease would recur, and soon be as bad as ever. The symptoms had been most speedily relieved on coming to the salt water at New York or Boston, and under such circumstances almost entirely disappeared. The air of Philadelphia was less beneficial, but no permanent relief was experienced as long as exposure to poison was renewed on her return home.

The marked symptoms in this case seemed to be of the mucous membranes and the nervous system, to be increasing in severity, alleviated by absence,

but returning on fresh residence, and so apparently due to a local cause. There was no malarial influence in the neighbourhood; the air, though somewhat damp, was pure and healthy; no imperfect drainage. On examining the paper of the room, I found it heavily loaded with arsenic. The patient now recalls the fact that no room in the house was so difficult to clean as her bed-chamber, and servants had made similar remarks. She herself found it almost impossible, for some reason unknown to her, to remain in her room, from the sensation of extreme exhaustion.

CASE II. The husband of this lady had occupied the same room, but his frequent absence from home on business and his out-of-door life had given him less exposure. Previously healthy, he had, soon after his occupancy of the room, begun to have tonsillitis, with dry tongue and mouth, and finally these symptoms continued throughout nearly the entire winter. He increased very markedly in weight, became dyspeptic, and had a foul breath, with a general sensation of malaise. He at last occupied another room at night, and was at once relieved, and has had no sore throat to this day.

CASE III. Mrs. B., an amateur artist, had in like manner a bright green paper on her studio. After spending some time in her room, in which she was occupied several hours each day, she would come out thoroughly exhausted; was very 'logy,' became bloated, and was generally running down. For some time she had had an ulcer on the face, which had not yielded to medical treatment. The library was hung with a green paper of a dangerous hue, and the bed-chamber with still another. A flock paper was also employed in some part of the house—where I do not know. The papers on the studio and chamber, as determined by analysis, are heavy with arsenic; that on the library contains a smaller amount, and a considerable quantity was found in the flock paper. The patient went to New York for some weeks, and remained while the paper was being removed and her house repaired. She speedily improved in health, the ulcer on the face took on a healthy action and was quickly cured, and the sensation of exhaustion disappeared.

CASE IV. Mr. B., the husband of this lady, being less exposed, suffered less, but he was for a considerable time the victim of conjunctivitis, which disappeared on removing the paper from the walls.

CASE V. The case of Mr. C. was very similar to that of the lady first mentioned. His case, however, was marked by more violent febrile manifestations and delirium, and he was for some time in danger of his life. One eye was lost by the sequelæ of conjunctivitis, and the other permanently injured. He was for a long time unable to sleep. A light green paper was on his chamber and sitting room. His removal from the house put an end to the reception of the poison. He is now much better, is recovering strength, flesh, and appetite, and his ability to sleep is now restored.

CASE VI. Mrs. C., the wife of the above, for the three years they had inhabited the arsenic-rooms, had had more or less sore throat, for which she was unable to account. During the first six months after leaving the rooms, she was much better, and at the end of a year was entirely well, and now has no trouble.

CASE VII. Mrs. D. had a green paper on her library, and another on the dining-room. I tested both, and found much arsenic in the former, and a

less amount in the latter. The next day these papers were removed from the walls, and a tendency to dysenteric diarrhoea, which had caused much trouble, at once diminished, and the attacks have been much lighter. Two canaries had died in the library without known cause, except that they showed signs of poison.

CASE VIII. Mr. E. (not my patient), who had slept in a room with a bright green paper for some years, was seriously ill, with symptoms referred to the nervous system and digestive organs. I never saw the patient, but am led to believe the symptoms were of such character as to be due to arsenic. He went to Europe for a change, and another gentleman, who took the house furnished, desired me to examine the paper. I did so, and found it loaded with arsenic.

The paper in the case first mentioned was not removed from the wall until after the marked convalescence of the patient in another room, to which she had been carried. Three or four persons were occupied in the work. One man got a sore mouth, having been previously well, and knowing no reason to account for it; another had every symptom of a cold, and felt a general stiffness of his limbs; a woman was in the room for half an hour, and her throat, previously entirely well, became rough and remained so for some days. A paper-hanger in the same neighbourhood remarked that his mouth was always sore when he put on green paper, and his men often spoke of their eyes becoming inflamed and their hands ulcerated.

I do not feel called on, in relating these cases, to enter upon the discussion of various points which naturally suggest themselves. The method of dissemination of the poison, the susceptibility of some persons to its influence and the immunity of others, and other points, have been often considered, and an opinion has been formed in the matter in the mind of every practitioner of medicine. One point, however, seems worthy of our attention, and cannot be too strongly urged; the necessity of sanitary measures to avert the evils arising from the use of arsenic in wall-papers and other articles of domestic and personal use; the duty of the physician to his patients and the community in warning them against the use of such articles, and the obligation incumbent on the State to enact and enforce laws for the protection of the people from dangers which we know to be insidious, but powerful for great peril to all those exposed to their influence.

It may be true in our land, where 'liberty runs mad,' that the view expressed by Dr. Draper, 'that the rights of individuals and of industrial pursuits are deemed too sacred to allow of excessive restriction, and a prohibitory law to affect the manufacture or use of arsenical pigment would be of questionable force,' a view in which, so far as this particular subject goes, I am inclined to disagree with him. Legislation, with the object in view of preventing the use of arsenical papers, has been employed in some of the more despotic nations of Europe, where the care of the citizen is considered of the utmost importance to the State. The case of the gentleman who returned to his house to find it in the possession of the sanitary police, engaged in removing a beautiful arsenical paper which he had just applied to his walls, is in point. The laws relating to slaughtering cattle, and preparing meat for the market, met with vigorous opposition a few years ago, but they are now looked on, even by the butchers themselves, as

highly salutary, and no hindrance to private rights or emoluments.

The fact that the most beautiful, the most delicate, and the most easily manufactured green colour is produced from arsenic, will always offer a strong incentive to manufacturers of wall-paper, to painters, makers of cloth fabrics, confectionery, card stock, and other materials in the arts.

As an adjunct to legislation, or to take its place, if such a course be impossible, it seems incumbent on physicians to act as instructors to the community. I fully agree with Dr. Draper, to quote once more from his report, that 'if there be awakened in the community some appreciation of the dangers which belong to the indiscriminate use of emerald green colours, there will be no need to invent methods of repression in behalf of the public health; for reasonable people, informed concerning the risks, will not be likely to test their own tolerance of arsenic or to subject their children to it. The demand ceasing, the supply will cease, and a correct taste in colour will find its gratification in agents which possess no poisonous character.' It is safer, however, to consider that a certain proportion of the community is not 'reasonable,' and that they are at once thoughtless and careless of the safety of themselves and of those around them. To gain the needed information the public requires frequent and often-repeated injunctions from those in whom they have confidence, and I feel it to be a duty of our state and local boards of health not to be neglected, to co-operate with physicians in extending a knowledge of the dangers of arsenic.

Arsenic green is a term which, it would seem, is sufficiently well understood by a considerable proportion of the intelligent members of the community. Large quantities of such papers are, however, still sold to go into the country and to those less careful of the hygienic condition of their households. It is less generally known that the presence of arsenic is not confined to green papers alone, and I show you this evening a number of specimens of wall-papers of various hues which may be looked on as very innocent in their outward appearance, but which I have proved by analysis to contain arsenic in considerable amounts. Many of them have a greenish hue, and in such the arsenical pigments have been used to tone down other colours. It is safe to consider that all wall-papers which contain arsenic, in any proportion whatever, are dangerous elements, in the light of modern sanitary hygiene.

SCHIFF ON POISONING BY FUNGI.

In an article in *L'Imparziale* (nos. 11 and 13), abstracted in *Lo Sperimentale* for July, Professor Schiff remarks that it has been commonly thought that each species of poisonous fungus produces its own special symptoms. An analysis of the phenomena observed, however, shows that such a distinction is inadmissible, since all the differences can be reduced to varieties in the degree of action on different systems of the organism. It is indeed probable that there is in all poisonous fungi one fundamental deleterious principle, and this is probably muscarine, discovered by Schmiedeberg of Dorpat in the *Amanita muscaria*. Other noxious principles, which may co-exist, and vary in different species of fungi, account for the differences which may be presented in the symptoms of individual cases of poisoning.

Muscarine, in the first instance, produces abundant salivation, due especially to an increase of the secretion of the submaxillary gland, while the increase in the secretion of the parotid gland is less. These observations, however, made by Schmiedeberg and by Schiff, who experimented on dogs and cats, are not applicable to man, who in this respect more resembles herbivora, and especially ruminants. This increased salivation, due to the action on the vaso-motor nerves, persists in poisoning by fungi even after the nervous trunk has been divided, which indicates perhaps that the poison acts on the peripheral nervous ramifications.

Muscarine at the same time exercises a depressant action on the heart; the pulse generally becomes larger and slower. With a small dose of the poison, however, there is generally a period of increase in the number of pulsations, and the duration of this period is the longer, the smaller the dose of poison administered. In dogs, the pulsations fall from 140 to 100, 60, 40, and then more slowly, till at last they amount to only nine in the minute. This has been confirmed by various other observers.

With the diminution of the cardiac pulsations, the blood-pressure is reduced. This cannot be considered as dependent on the unfrequency of the pulse, since it is observed where the number of pulsations remains stationary or is even slightly increased; it appears to be due rather to dilatation of the small peripheral vessels.

The respiration is also depressed in proportion to the depression of the pulse; it cannot, however, be said that these phenomena are dependent one on the other. In reptiles, indeed, and in frogs, there may be a very slight change in the respiration, the pulse being very unfrequent.

The abdominal secretions and the movements of the intestines appear to increase under the influence of muscarine. The increase of the secretions is shown in the mucous evacuations, which are also sometimes tinged with blood. Abdominal auscultation, and direct inspection of the bowels after laying open the abdomen, demonstrate the increased intestinal movement; which, however, does not consist so much in an increase of the normal peristaltic action, as in partial, and to a certain extent tonic, contractions.

These are the chief symptoms of poisoning by muscarine. It may be added, the animal which presents these symptoms manifests also partial contractions in the tail and in some of the subcutaneous muscles, due to feeble fibrillary movements of the muscles. Besides, in animals which present the phenomena of poisoning with muscarine, the action of the heart is more easily arrested under the slightest electrical or mechanical irritation of the pneumogastric nerve.

With poisonous fungi, when the stomach is not even freed from them by vomiting, there are, besides the symptoms described as produced by muscarine, others dependent on the central nervous system, on which muscarine does not appear to have any direct action. In poisoning by *Amanita muscaria*, besides the symptoms described, there are restlessness, convulsions (which soon affect the respiratory muscles), dilatation or contraction of the pupils. These symptoms, which resemble those produced by opium and by morphia, have been observed in man.

Respiration is more disturbed by muscarine than by the ingestion of poisonous fungi; and this, perhaps, depends not only on defective innervation, but

also on the mechanical obstruction produced by the accumulation of mucus. This difference of action depends, perhaps, on the fact that muscarine given in the isolated form, is rapidly absorbed and carried into the circulation, while its absorption takes place slowly when poisonous fungi are administered.

There appears to be a very close analogy between the action of Calabar bean and that of poisonous fungi. Calabar bean, however, according to Schmiedeberg, increases the blood-pressure, and, according to Schiff, produces in a greater degree fibrillary contraction of the muscles. There is an alteration of vision, that is, the pupil is dilated or contracted, without defect in the power of accommodation, either from the internal administration of fungi and of muscarine (Böhm of Dorpat) or from Calabar bean and eserine (Schiff). It is only when the extract of Calabar bean or eserine is directly injected into the eye, that contraction of the pupil is always produced (Schmiedeberg, Schiff, etc.).

The symptoms described above are opposite to those which are produced in poisoning by atropia, daturia, and by certain *solanaceæ*. This antagonism has been denied by Rossbach; but it exists; and Schiff has made some experiments to ascertain whether *solanaceæ* are antidotes to poisonous fungi. In the only four experiments which he has been able to make, he has administered datura stramonium to animals poisoned with fungi mixed with fat. Although the pulse was extremely unfrequent, the breathing was very difficult, there was almost absolute immobility, and the animal appeared moribund, yet in one case, only three minutes after the administration of the antidote, the number of pulsations increased, the respiration became more regular, the secretions were diminished; and this improvement gradually became more perceptible, until at the end of an hour and a half there was merely somnolence with partial agitation, which had entirely disappeared at the end of eleven hours. In another case, the administration of daturine produced immediate relief of all the symptoms, except of the cerebral symptoms, which were increased. Daturine, as Schiff has proved by experiments on animals and on himself, produces cerebral phenomena analogous to those arising from poisonous fungi. Daturine produces a remarkable diminution of the secretion of urine. As regards all the other symptoms of poisoning by fungi, however, daturine and the alcoholic extract of stramonium are antagonistic.

It is indeed probable that two toxic substances exist in poisonous fungi; one, muscarine, produces on the circulation, respiration, and secretions, an action opposite to that of daturine and of atropine; while the other produces on the central nervous system an action analogous to that of atropine and of daturine. Some years ago Schiff gave to some guinea-pigs a dose of stramonium, and then a dose of poisonous mushroom, twice as much as was sufficient to cause death; none of the special symptoms of poisoning by muscarine were produced.

He therefore recommends in cases of poisoning by mushrooms the use of atropine, of daturine, or of stramonium in substance or in the form of alcoholic extract, in quantity proportioned to the quantity of poison injected. Lauder Brunton was the first to propose this treatment, basing it on the experiments of Schmiedeberg on the antagonism between muscarine and daturine. Schiff has demonstrated by direct experiment the justice of this proposal.

A. HENRY, M.D.

CORONA ON THE ANTAGONISM BETWEEN MORPHIA AND ATROPIA.

Dr. Corona, in an article in the *Giornale di Medicina Militare* for April and May, describes some experiments which he has made on dogs, rabbits, and frogs, with regard to the antagonistic action of morphia and atropia. The following are the conclusions at which he has arrived.

a. Atropia quickens respiration in an extraordinary manner; morphia, on the other hand, retards it greatly, and modifies it, the inspirations becoming large and deep, and the expirations slower.

b. Morphia produces sleep and deep coma; atropine, on the contrary, produces severe convulsions, but never sleep, in dogs and rabbits.

c. Morphia quickens the movements of the heart; atropia renders them slow.

d. While morphia accelerates the heart's action, the temperature (generally taken in the rectum) falls; atropia, on the other hand, diminishes the heart's action, while the temperature remains stationary or is slightly increased.

e. In the action of atropia, the dilatation of the pupils is the most marked symptom, as sleep is in the case of morphia; with morphia, on the other hand, the pupil is sometimes dilated, sometimes stationary, sometimes contracted. Dr. Corona finds, 1. that dilatation of the pupil occurs in animals principally when the dose of atropine introduced into the blood is relatively mild; 2. that, when the dose of atropine injected into the circulation is large, dilatation does not occur, because both the circular and radiating fibres of the iris are paralysed; 3. that dilatation of the pupil is produced by the injection into the eye of a solution containing a very small fraction of a milligramme of atropia; 4. that the dilatation of the pupil constantly occurs, even when a large quantity of atropia is injected gradually, the other symptoms of poisoning being sudden, in consequence of the rapid elimination of a large portion of the poison.

f. Morphia never produces vaso-motor paralysis; atropia always does, as is clearly shown by observing the ears of rabbits poisoned with it. As regards this: 1. The congested vessels of the ear constantly return to the normal state under the influence of galvanisation of the cervical sympathetic, in rabbits previously poisoned with atropia, and in which the vaso-motor paralysis is at the maximum. 2. During the galvanisation of the sympathetic, the constriction of the vessels is followed by a diminution of temperature, corresponding to the increase attending the vaso-motor paralysis of the ear. 3. In rabbits, 20 centigrammes (0.3 grain) of neutral sulphate of atropia are required on an average to produce vaso-motor paralysis, and the injection must be made at one time; otherwise as much as 70 centigrammes (little more than a grain) may be used without producing this phenomenon, if it be injected in doses of 10 centigrammes at intervals of five minutes.

g. Morphia, while it constantly produces sleep, leaves reflex action intact, and sometimes exalts it; atropia depresses reflex action, and always produces paralysis of the posterior part of the body in animals.

As regards necroscopic results, the following conditions were always observed.

h. The lungs, liver, and spleen, were normal in both cases. The heart and large vessels were always

full of blood; but this was coagulated in poisoning by morphia, fluid and blackish in poisoning by atropia. The meninges in both cases were always congested, while the brain-substance was constantly found to be anæmic. The medulla oblongata and the tubercula quadrigemina were never found hyperæmic, while the meninges covering them were so.

i. As regards the toxic dose, there was very great variation both in regard to the age and the race of the animal. In rabbits, morphia was sometimes fatal in doses of 20 centigrammes (0.3 grain); whilst sometimes as much as 50 centigrammes (0.75 grain) was borne. Sleep and slowness of respiration were, however, constant results even of very small doses. In dogs, the toxic dose was much less. Atropia was tolerated in very large doses; in rabbits as much as one gramme (15 grammes). It was, in many cases, fatal in doses of 50 centigrammes; never in less, except in young and very small animals. Large doses of atropia were tolerated on the first two days, but the animal did not survive the third. Even with small doses, the remarkable quickening of the respiration, the dilatation of the pupils, and the vaso-motor paralysis, were observed.

Experiments made on the pneumogastric nerves during the poisoning, whether by morphia or by atropia, showed that the antagonistic respiratory changes always proceeded from the centres of respiration.

k. Finally, with regard to the result of experiments on the alleged antagonism of atropia and morphia, Dr. Corona makes the following remarks. 1. Morphia was always capable, even in very small doses, of removing the symptoms produced by atropia, and of producing sleep. 2. During morphia sleep, very large doses of atropia did not in the least alter the symptoms due to morphia, nor was the sleep ever found to cease. 3. When atropia was injected in small doses at intervals of ten minutes, although the total quantity was large, its action was more rapidly extinguished by small doses of morphia, than when atropia was injected in a dose of not less than 20 centigrammes. 4. The injection of the two poisons into the veins showed that a much smaller dose was sufficient to produce rapid and grave poisoning; but even then the morphia produced its action instantaneously, and its symptoms always superseded those of atropia. 5. The injection into the veins of large doses of atropia and very small doses of morphia was always followed by sleep, and the manifestation of the symptoms due to atropia was tardy. 6. In all cases, after the disappearance of the symptoms due to morphia, those due to atropia appeared, in intensity proportionate to the largeness of the dose administered for the purpose of counteracting the symptoms due to morphia.

From these results, Dr. Corona concludes that a partial physiological antagonism may be recognised, but that the idea of a mutual therapeutic antagonism cannot be accepted.

He recommends in poisoning by atropia the injection of morphia and its salts, both into the veins and by the hypodermic method, but altogether disapproves of the idea of combating morphia poisoning with atropia, both because very large doses of the latter are incapable of removing the symptoms produced by morphia, and because, even if the latter are temporarily relieved, the still more deadly symptoms due to atropia supervene.

A. HENRY, M.D.

CHARCOT ON THE LOCALISATION OF CEREBRAL DISEASES.

(Continued from page 154.)

On resuming this course of lectures, M. Charcot once more directs the attention of his hearers to the anterior region of the central ganglia, in order to study more closely from the points of view of anatomy and physiological pathology those lesions which are produced therein. This region he has already designated by the term lenticulo-striate, to distinguish it from the posterior or lenticulo-optic region; it comprehends the two anterior thirds of the internal capsule, the head of the nucleus caudatus, and about the two anterior thirds of the nucleus lenticularis. He reminds his hearers of the often repeated observation already noticed in this course, that common motor hemiplegia without anæsthesia is the consequence of lesions affecting the parts just enumerated, on condition that the lesion causes the destruction or the rapid compression of the nervous elements; while, however, lesions even if extended and great, which remain limited to the sphere of the ganglia, cause only slightly marked and passing symptoms; and on the other hand relatively slight lesions affecting the white matter (internal capsule) cause a hemiplegia not only well marked, but of long duration and often incurable. He goes on to seek for the explanation of these differences, and considers first the cause of the relative intensity, and afterwards that of the duration of the symptoms.

In considering the first point, that is, the relative intensity or gravity of the symptoms, he refers to the anatomical constitution of the internal capsule, which is made up of, first, direct peduncular fibres, or fibres which run from the cortex to the peduncle without any communication with the caudate or lenticular nuclei; second, indirect peduncular fibres, which, on the contrary, take their origin in the lenticular nucleus, or the caudate nucleus, and have no relation with the cortex; for the moment, the bundles of fibres passing from the cortex to the nuclei are left out of consideration. He supposes that both the direct and the indirect fibres are centrifugal fibres, transmitting to the periphery motor influences, developed either in the cortex of the brain, or in the lenticular and caudate nuclei. On this hypothesis it is easy to understand how a lesion operating on the inferior portion of the capsule in the neighbourhood of the base of the corona radialis will have for its effect the suppression at once of the influence of the cortex and of the two nuclei, while, on the contrary, a lesion limited to one of the nuclei leaves unimpaired the action of the cortex and the other nucleus. He does not allow undue importance to this theoretical view, but he points out that it agrees with clinical observations made on man, and is not contradicted by experiments on animals, more especially in the higher animals, as the dog. In experiments made on the brains of dogs by MM. Carville and Duret, the following results were obtained. 1. Ablation of the grey matter in the so-called motor centres of the cortex determines a temporary paresis of the limbs on the opposite side of the body. 2. The extirpation of the caudate nucleus determines an analogous but more marked paresis. 3. If the lesion operate, on the other hand, upon the inferior portion of the capsule, it produces a well-marked paralysis of the opposite side of the body. Also, he remarks, it may be well to recall the fact that MM. Carville and Duret, as well as M. Veyssière, found that lesions of the posterior part

of the capsula interna produce, as has been observed in man, crossed mehi-anæsthesia.

These considerations will also serve to explain the second point, namely, the relative duration of the symptoms, which are temporary if the lesion be limited to the substance of the nuclei, while, on the other hand, if it involve the capsule, they are of long duration, and often even absolutely incurable. It is easy to understand that the fibres of the capsule being intact, the nuclei and the motor centres can mutually supplement each other's function, and heads, not only can one nucleus supplement the other, but such supplementation may occur between different parts of the same nucleus. It is established, at least for the nucleus caudatus, that partial destructive lesions operating upon different parts of this nucleus produce uniformly a more or less marked transitory but total hemiplegia, affecting both the limbs and the face. It appears, as Dr. Hughlings Jackson has said, as if each part of the corpus striatum represented in miniature the entire ganglion. Experiments, moreover, have shown that partial excitation of the caudate nucleus produce movements of all the opposite side of the body, and not dissociated movements, localised, for example, in a limb or a part of a limb. On the other hand, in the case of a destructive lesion of the internal capsule, only a slow regeneration of the nervous elements can permit the gradual re-establishment of its functions. This process of repair, if it really sometimes occur, does so only in exceptional cases; and, as a rule, lesions which destroy to a certain extent the motor fibres of the capsule, have for their almost necessary consequences the production of a fasciculated lesion, which commencing immediately below the injury may be followed on the same side in the base of the peduncles, the pons Varolii, the anterior pyramid, to the decussation in the medulla, and below this on the opposite side along the lateral column to the lumbar enlargement.

These secondary degenerations or descending scleroses are worthy of some attention, for they are undoubtedly among the principal causes of the persistence of motor paralysis, and also, he believes, for the most part occasion the permanent or late contraction which occurs in these cases. In the first place, it is remarkable that localised lesions are not all equally capable of determining the production of consecutive scleroses; thus, some never do so, such as lesions which remain limited to the substance of the ganglia; on the other hand, those affecting the fibres of the internal capsule, in their course between the nucleus lenticularis and the nucleus caudatus, are inevitably followed by secondary sclerosis.

This remarkable fact was clearly made out by Türck in 1851, and since then it has been confirmed by MM. Vulpien and Charcot, and also by M. Boucard. The following facts have also been proved by the same observers. 1. Lesions situated outside the ganglia in the centrum ovale, if they attain certain dimensions, also produce descending sclerosis if they are not too far off the base of the corona radialis. 2. Very superficial lesions of the cortical grey matter, such as those accompanying meningitis, do not produce descending sclerosis. 3. On the other hand, cortical lesions of some depth and extent implicating both grey and white matter without any participation of the central ganglia determine under certain conditions consecutive scleroses as pronounced as those dependent upon a lesion of the anterior part of the internal capsule. These con-

ditions are that the lesion implicate the two ascending convolutions (ascending parietal and ascending frontal) and the adjacent parts of the parietal and frontal lobes. Lesions affecting the occipital lobe, the posterior part of the temporal lobe, the sphenoidal lobe, or the anterior regions of the frontal lobe, are not followed by these descending sclerosis. 4. The seat and extent of the lesion appear to be the two fundamental conditions, the nature of the lesion not having a marked influence provided that it is destructive, and not as in the case of certain tumours which simply push back and separate the medullary elements without interrupting their continuity.

The lecturer next draws attention to certain facts in the anatomy of these sclerosis. They always occupy one-half of the system of the lateral columns; they always affect its whole length to the lower end of the lumbar enlargement; they are always descending, taking origin below the point of lesion, and not to be followed above it. Some of the most prominent characteristics may be observed with the naked eye, such as flattening and narrowing of the corresponding *crus cerebri*, and on section a grey band running through it which never extends beyond the *locus niger*; the grey colouration disappears at the pons Varolii, but is met with again in the medulla, where it occupies the anterior pyramid in the whole of its length on the same side; the pyramid is otherwise thinned and flattened; lower down the denticulations in the medulla appear more distinct than on the normal side; below the decussation in the half of the cord opposite to the lesion, in the situation of the lateral columns, the sclerosis appears in the form of a triangular space of a grey colour outside and in front of the posterior horn, and gradually diminishes in size as the sections are made lower and lower in the cord. Microscopical sections of the cord, properly hardened and prepared, show more exactly the topography of the lesion. The other white fibres and the cornua remain perfectly intact, while both the anterior and posterior roots and the meninges show no trace of alteration. He remarks that there exist analogies from an anatomical point of view between these secondary sclerosis of cerebral origin and those symmetrical primary sclerosis of the lateral columns which he described last year, *à propos* of spinal muscular atrophies. But there are also differences which must be noticed; thus, in this primary sclerosis the lesion is necessarily double, occupying both lateral columns, and in addition it extends wider, involving not only the cerebral but the proper spinal fibres of the lateral columns. Moreover, primary sclerosis has a great tendency to invade adjacent regions, sometimes the white matter, but above all the anterior cornua, which does not occur in secondary sclerosis.

On the other hand, analogies may be noticed in the contractions, at first transient, then permanent, of the limbs with spontaneous or provoked tremors in both diseases. M. Charcot considers that it is not the contraction of the cerebral cicatrix, as Todd thought, that accounts for the appearance of late contractions in hemiplegic subjects, but on the contrary, he considers them due to a chronic myelitis of the lateral columns consequent on the cerebral lesion. Although the sclerosis is developed in consequence of a cerebral lesion, it may acquire to some extent an independent existence; and by reason of this independence, the lesion extends beyond its usual limits to invade neighbouring regions, the cornua, for ex-

ample, producing in this case important modifications in the symptoms, the muscles undergoing a more or less rapid atrophy, and the rigidity caused by contraction giving place to flaccidity. MM. Pierret and Charcot have observed many examples where, in addition to sclerosis of the lateral columns, there has been invasion of the anterior cornua resulting in destruction of their large cells. The invasion of the posterior horns might explain in the same manner the appearance of certain partial anæsthesiæ in ordinary hemiplegia. And, again, the extension of the irritative process either to the whole extent of the lateral column of the same side or even to the lateral column of the opposite side, would account without doubt for the fact that, contrary to common observation, contraction sometimes predominates considerably at a given time in the lower extremity, or even occasionally extends to the lower extremity of the opposite side. Although he has only been considering sclerosis secondary to lesions of the central masses, those produced by lesions of the cortex do not differ from them in any respect. He recalls to mind that the existence of direct peduncular fibres, that is to say, fibres which after emerging from the base of the *crus* traverse the internal capsule without entering the nuclei of the central masses and stop only at the cortical substance, has been admitted as a highly probable hypothesis. Besides the arguments already put forward in its favour it is supported by the experiments already quoted of M. Gudden who, having removed the anterior parts of one hemisphere in very young animals, the central masses, optic thalamus, and corpus striatum remaining intact, found, on examining the parts eight months afterwards, a remarkable atrophy of the internal capsule on the same side, which certainly would not have occurred if the internal capsule were exclusively composed of indirect peduncular fibres terminating in the central ganglia. MM. Carville and Duret found in one of their dogs that a lesion had by chance destroyed the white substance of all the frontal parts of one lobe without directly affecting the central ganglia or the internal capsule; in this case there was a well marked atrophy of the base of the *crus* of the pons and of the anterior pyramid on the corresponding side. The existence in man of these direct fibres seems to be attested by the production of those secondary degenerations which, as has been remarked, develop in consequence of extensive and deep lesions of the cortical grey matter. M. Charcot's observations made at the Salpêtrière have led him to believe that these direct fibres pass only to the ascending parietal and frontal convolutions and their neighbouring parts, for lesions of the cortical substance in these parts only were followed by permanent hemiplegia and secondary sclerosis; parts which correspond to those in the brain of the monkey which have been mapped out by experiment as the centres called psycho-motor, and in which the cortical grey matter contains the largest-sized pyramidal cells.

MOSSO ON THE HYDRAULIC MOVEMENTS OF THE IRIS, AND ON THE ACTION OF SOME SUBSTANCES ON THE PUPIL.

A. Mosso (*Accademia di Medicina di Torino*, 1875) regards as hydraulic movements those movements of the iris which are dependent on filling and emptying the vessels of this structure. The results

of his experiments coincide with those of Grünhagen. If a half per cent. solution of common salt, serum, or defibrinated blood be injected under a high pressure through the carotids into the head of a rabbit two days after death, a change in the pupil occurs. The pupil shortly after death can be dilated by the introduction of a solution of atropine, and can be preserved by taking special precautions.

The hydraulic movements depend upon the arrangement of the vessels of the iris. Leber had already shown how the arteries of the iris collectively arise from the large corona iridis, and run in a radial direction towards the margin of the pupil. Most of them bend round in an arched manner to terminate in the origin of the veins. In order to explain the mechanism of the hydraulic movements from the arrangement of the vessels of the iris, Mosso prepared an artificial iris from a thin walled caoutchouc tube, which was arranged upon a plate of cork. The convolutions of this tube ran here and there between two concentric circles. On the outer circle, which corresponded to the large corona iridis, they were fixed with needles, and at the margin of the pupil they were left free. With this arrangement it can be shown that filling of the vessel corresponds with a diminution of the pupil, and with every emptying of the tube the artificial pupil dilates. In this way Mosso explains many movements of the iris, which were formerly insufficiently explained by the action of muscles and nerves.

Every dilatation of the vessel produces myosis, whilst its contraction is followed by mydriasis. These results the author can confirm on man by means of his plethysmograph. Mosso had formerly found that every deep inspiration is followed by a contraction of all the vessels. If through a small hole made in a visiting card by means of a needle, one looks at a white wall, the movements of one's own iris may be observed. By this simple method the author observed on himself how every deep inspiration and every contraction of the vessels was connected with a dilatation of the pupil.

The myosis depends sometimes only on paralysis of the vessels, and it is a constant phenomenon in the action of substances such as chloroform, ether, chloral, morphia, etc., which dilate vessels and produce sleep. Conversely, mydriasis occurs every time, when either by poisons or through other conditions, the vessels contract.

Lastly, the author has found that when the pupil has reached the maximum of dilatation by electrical stimulation of the sympathetic in the neck, electrical stimulation of the oculo-motor within the cranium, or an intense light, can contract the pupil, without, however, producing the minimum of contraction. Conversely, when by action of light the pupil has been almost caused to disappear, it can be slightly dilated by stimulation of the sympathetic, without, however, attaining its maximum.

W. STIRLING, D.Sc., M.D.

SCHMIDT ON THE RELATION OF THE COAGULATION OF FIBRIN TO THE COLOURLESS ELEMENTS OF THE BLOOD.

A paper on this subject, by Alexander Schmidt, is contained in *Pflüger's Archiv*, vol. xi. p. 515, and *Centralblatt für die Medicinischen Wissenschaften*, no. 25, 1876.

1. *On the Origin of the Fibrin-Ferment.*—It can be easily shown that the coloured corpuscles have nothing whatever to do with the fibrin-ferment. 1. There are fluids which, though containing no coloured corpuscles, coagulate after removal from the body; from the serum, by precipitation by alcohol, a solution of the ferment may be prepared. 2. Plasma of horse's blood poured off from the red blood-corpuscles which had been allowed to subside, contained at the moment of their separation from the blood-corpuscles only traces of the ferment. Nevertheless it coagulated at the ordinary temperature, and produced serum containing a ferment. 3. If, for the preparation of the fibrin-ferment, defibrinated horses' blood be employed in which the corpuscles have been allowed to subside, solutions of less potency are obtained from the lower layers consisting almost entirely of blood-corpuscles than from the upper. In non-defibrinated blood from the lower layers consisting of blood-corpuscles, no active solution of the ferment can be obtained. The source of the fibrin-ferment is the colourless blood-corpuscles; it arises from these after removal of the blood from the body, and then passes into the fluid. The proof of this is shown by filtration of the plasma. If the blood of a horse be caught in a glass vessel, placed in ice, and the blood-corpuscles allowed to subside when the temperature has fallen to 0° C., and the plasma filtered through several sheets of filtering paper into a vessel at 0° C., a perfectly clear, generally somewhat red coloured filtrate quite free from blood-corpuscles, which only shows the slightest tendency to the formation of fibrin, is obtained. If a portion of filtered and of non-filtered plasma be exposed at the ordinary temperature of the room, the former coagulates much later than the latter, and the coagulation does not end for a very long time. Complete absence of coagulation is therefore not to be expected, because the blood-corpuscles begin to form the ferment at once after their removal from the body, and this process cannot be instantaneously prevented by cooling. When the filtered fluid is allowed to stand, the amount of the fibrin remains unchanged, whilst that of the non-filtered fluid continually increases. This difference between filtered and non-filtered plasma can be tolerably completely prevented, if the plasma be warmed to 10° or 20° Cent. for several minutes before filtration, and then cooled. The residue extracted with water is dissolved in weak alkaline fluid, and consists of a weak opalescent solution of fibrinoplastic substance, containing only traces of ferment. Corresponding to these observations, transudations which appear to be turbid through the presence of colourless elements regularly coagulate; whilst perfectly clear transudations show no tendency to spontaneous coagulation, which, however, occurs on the addition of the ferment. The dependence of coagulation on the colourless corpuscles can also be shown by adding various quantities of suspended colourless corpuscles to the plasma; that portion to which the largest number of corpuscles has been added coagulates much more rapidly than the others. If two portions of the same plasma be taken, and one of these be left to itself, whilst the blood-corpuscles in the other are distributed regularly by repeated stirring, the subsided layer coagulates first in the first quantity, then the second quantity, and lastly, though much later, the fluid standing above the coagulum. This experiment shows that the impulse to coagulation does in fact proceed from the

lymph-corpuscles. The action of non-crystallised hæmaglobin in accelerating coagulation occurs more pronouncedly, the smaller amount of ferment in solution, and the slower it coagulates without the addition of hæmaglobin. Solutions of crystallised hæmaglobin do not produce any accelerating effect.

II. *On the Origin of Fibrino-plastic Substance.*—If plasma be filtered and the residue extracted with water and then treated with slightly alkaline water, a filtrate is obtained which contains a considerable amount of fibrino-plastic substance in solution. The residue on the filter consists only of colourless blood-corpuscles, from which by solution fibrino-plastic substance has exuded. The objection that the filter residue contains fibrino-plastic substance, which has no connection with the colourless corpuscles, and excreted in consequence of the cooling, is refuted by the fact that filtered plasma is able to dissolve fibrino-plastic substances added to it. Fine granules are excreted from the plasma. These do not consist of fibrino-plastic substance, but are the remains of disintegrated colourless corpuscles which are constantly mixed with the fibrin, and at the first are easily recognised as such, but in the later stages of coagulation disappear more and more. The decomposition products of the colourless corpuscles increase the weight of the fibrin. This fact can be proved by estimating the amount of fibrin in the filtered plasma. A filtrate completely free from fibrino-plastic substance is never obtained, because the disintegration of blood-corpuscles can never be entirely avoided. Nevertheless the author obtained from filtered plasma only 0.35—0.45 per cent. against 0.5—0.7 from the non-filtered. The amount of fibrin obtained from the filtered plasma when a solution of fibrino-plastic substance is prepared from the colourless elements and added to the filtered plasma. The difference in the quantity of the fibrin produced becomes much greater when the plasma before filtration is treated with twelve to fifteen times its volume of water. In this case also by the addition of fibrino-plastic substance the amount of fibrin is again increased. Plasma diluted with ten to fifteen times its volume of water remains fluid for an unlimited time at 0° Cent. The colourless corpuscles sink rapidly, so that the supernatant fluid can be poured off after twenty-four hours, and the blood-corpuscles can be purified by washing with cold water. If after washing they be mixed with a solution of fibrinogen, or better, if fibrino-plastic substance precipitated by carbonic acid or acetic acid and suspended in water be added to the fibrinogen fluid, there results an exceedingly slow coagulation, because only traces of ferment are present.

We have now to ask whether the colourless corpuscles also contain fibrinogen. This question is to be answered in the negative for mammalian blood; for if the washed corpuscles be dissolved in weak alkali and fibrin-ferment be added, coagulation never occurs. On the contrary, the solution obtained from the corpuscles of the blood of birds and of amphibians always exhibits a spontaneous coagulation. The fibrin of the blood of amphibians is characterised by its greater solubility in alkalies and acetic acid, but becomes, however, less soluble by washing with water. Frogs' blood coagulates very rapidly, but again becomes fluid in the course of forty-six hours by the fibrin dissolving in the alkaline serum. If the blood-corpuscles be allowed to subside in the defibrinated blood, and the serum poured off, by the addition of water and the solution of the blood-cor-

puscles, a new coagulation occurs, which again becomes dissolved in several hours. The blood-corpuscles, therefore, of the frog undoubtedly contain fibrinogen; and also those of the bird. Whether this proceeds from the colourless or the coloured corpuscles is doubtful. The assumption that similar conditions are true for the coloured corpuscles of mammalian blood, can at present be neither refuted nor proved. WM. STIRLING, D.Sc., M.D.

SINKS ON A CASE OF TRAUMATIC ANEURISM OF THE RIGHT SUBCLAVIAN ARTERY FROM GUN-SHOT WOUND: TREATED BY DIGITAL COMPRESSION WITH SUCCESS.

Dr. T. Sinks, of Leavenworth, Kansas, reports the following case in the *Richmond and Louisville Medical Journal*, January, 1876.

This is in many respects one of the most extraordinary and interesting cases of injury to a large artery which is contained in the annals of surgery. The patient, a man fifty-one years of age, was shot with a pistol carrying a bullet which weighed $\frac{1}{4}$ oz., and measured $\frac{3}{8}$ in. in diameter, at 10 P.M., May 10, 1875. It was fired so close to the man as to singe his face and whiskers—the clavicle was comminuted, and the bullet, passing across the subclavian artery, 'lodged somewhere in his body.' The occurrence took place in the opera; the wounded man walked up about six to ten steps, then twelve feet across a floor, and sat down on a chair, and then the surgeon, who was in the building, saw him. A stream of bright arterial blood was flowing up perpendicularly from the wound, 'about an inch in height and $\frac{3}{8}$ in. in diameter.' He fainted in about six seconds; respiration and pulse ceased, and he was thought to be dead. This might have been as much as two minutes after the receipt of the wound, but the time probably did not exceed one minute. Very shortly afterwards, a little feeble respiration recommenced, and in about fifteen minutes a feeble pulse could be detected in the left wrist. The surgeon had inserted his little finger into the wound immediately after it was exposed, and found that the bone was perforated by a circular opening with serrated edges, and was also fractured across; but he was immediately 'pushed away by the surging crowd around,' and no further examination was made at any time. The man lay in a state of great prostration for seven hours, during the first two of which he was completely blind, but sensible, and able to distinguish his friends by their voices; and then he underwent a series of depressions, in which the pulse 'became imperceptible, the respirations slow and laboured, the surface cold and clammy, with loud expressions of agony,' with intervening reaction. The frequency of these depressions became less, and after lying for seven hours, where he was first seen, he was well enough to be removed to his home, where a full hypodermic injection of morphia procured sleep, and at 10 A.M. (twelve hours after the receipt of the injury), he was undressed and put to bed. At that time a large and firm coagulum had formed around the wound. Thirty-two hours after the wound, it was found that a large traumatic aneurism had formed, which extended some distance above, and a greater distance below the clavicle with well marked thrill and bruit, but its exact limits could not as yet be defined. Auscultation revealed the existence of a large collection of fluid

in the posterior part of the right pleural cavity, leading to the inference that the costal pleura had been wounded. A consultation of neighbouring practitioners, including two army surgeons, was now held, to decide what course should be pursued. An attempt to find and tie the wounded vessel appeared too dangerous; the ligature of the first part of the subclavian would be exceedingly difficult in the state of the parts and by no means sure to cure the aneurism, besides that all known cases of this operation had proved fatal. It was therefore decided 'to watch the patient closely, preserve as nearly as possible absolute immobility of the shoulder, keep him on low diet for the purpose of subduing the impulse of the heart, hope for a sacculation of the aneurism and a closure of the wound without a degree of suppuration that would undermine the feeble security thus provided by nature, and to leave the question of an operation for ulterior consideration.' At the same time, arrangements were made for suppressing external hæmorrhage if it should supervene. This, however, was not the case. Several severe attacks of prostration during the next few days threatened his life; in the last of which he seemed to be dying, and, in fact, it was thought that he would be dead in a few minutes; but he slowly recovered, and from this time had no similar attacks. They were thought to be due to accumulations of blood in the pleura, from the injury; and it was believed that during the prolonged syncope which accompanied the last attack the injured vessels had become closed. The limb gradually recovered itself from this time, and in six weeks the respiration on that side was natural. The fracture became consolidated, and the wound healed after exfoliation of some fragments in six weeks, nor did any further bleeding take place. There was at first much numbness in the fingers of the right hand, which gradually subsided; but the second, third, and fourth fingers of the left hand from some unexplained cause lost sensation, and this had not been entirely regained at the date of the report. [It must be recollected that the course and position of the ball remained quite unknown.—*Rep.*] As the swelling subsided, the outline of the tumour became more plain, and in four weeks from the time of the injury it was quite defined; and now it was ascertained that pressure on the trunk of the subclavian against the first rib completely stopped the pulsation of the aneurism, proving conclusively that the vessel injured must have been the trunk, and not one of the branches which are given off at a higher point. The question now arose, between ligature of the third part of the subclavian artery (which would have been quite feasible) and compression. It was decided to attempt the cure by the latter measure; and on June 10 intermitting digital compression was commenced for fifteen or twenty minutes three times a day. This duration of pressure was all that could be borne, from the numbness and pain which it produced in the hand and arm. Great benefit seemed after a time to be produced by direct pressure on the sac also. On July 2 (he having in the interval been able to bear a longer continuance of pressure) continuous pressure was commenced and kept up for 186 hours, except a slight relaxation for eating and bathing; the pressure not being so strong as quite to check the flow of blood into the sac, 'but enough to stop the impulse or throb of the tumour.' On July 4, for the first time, the pulse was detected in

the right radial artery, and pulsation could be felt along the whole of the brachial. On July 11 compression was resumed, and continued as before—day and night—until July 22, when the soreness of the skin compelled its discontinuance. It was now possible to make out the outline of the artery and of the tumour. The former ran downwards and inwards, in reference to the wound, instead of obliquely towards the axilla; and the extremity of the artery was funnel-shaped, the aneurismal sac being bulbous and very little larger than the dilated artery. Very slight pressure sufficed now to stop all pulsation and thrill. No increase of thickness could at any time be detected in the walls of the sac, and it was believed that the cure was produced not by lamination of clot, but exclusively by contraction of the sac. On August 30 he was sufficiently recovered to be allowed to travel to New York, being instructed to maintain compression himself as long as any aneurismal bruit existed. The latter, however, had by this time become much more faint. It is unnecessary to follow the further history of the case, which presented no feature of interest. The author concludes with a short *résumé* of the more prominent features of interest in this extraordinary case, viz., the imminent danger from pressure of blood on the lungs, the remarkable absence of recurrent hæmorrhage and of all suppuration, and the great success of digital compression. The agents in carrying out this prolonged and difficult operation were the patient's wife and brother (and latterly himself) during the day, and four medical students and the clerks in the Post Office at night.

Dr. Sinks also refers to the writings of various authors, including the present reporter, to show the great dangers which beset any attempt to tie the subclavian under these circumstances, the possibility of successful compression, and the superiority of the digital to all other forms of compression. As an authentic account of recovery after a gunshot wound of the subclavian artery, the case has undoubtedly a very great value in surgical literature.

T. HOLMES.

DELAFIELD ON SOME FORMS OF DYSPEPSIA.

This is No. 4 of Vol. II. of a series of American Clinical Lectures, edited by Dr. E. C. Seguin, and published by G. P. Putnam's Sons, New York. Dr. Francis Delafield is known by his *Handbook of Post mortem Examinations*, and other pathological publications. In this clinical lecture he states that he believes it possible, in many cases, to distinguish between cases of dyspepsia dependent upon disease of the stomach, those due respectively to the condition of the small intestine and of the large intestine, and those due to disease of the liver. Those of the pancreas are less easy to locate. He does not deny that all the organs named may be involved in many cases.

The symptoms of dyspepsia due to an abnormal state of the stomach are—nausea, vomiting, pain, loss of appetite, eructations of gas and of sour fluid. The vomited matters consist only of food, or of food mixed with a sour fluid; of this the patient may vomit several quarts during each attack. The pain is regularly followed by a desire to vomit, and after this is done the pain ceases. A fragment of bread, not larger than a chestnut, remaining in the stomach, is sometimes sufficient to keep up the pain and retching for hours, until it is expelled. The

appetite is usually small, capricious, and unnatural. If the disease be of long standing and severe, the patients lose flesh and strength, and present a very deplorable appearance. The lesions consist in a chronic inflammation of the mucous coat of the stomach, with loss of power in the muscular coat. The inner surface of the organ is constantly coated with an increased quantity of tenacious mucus. The connective tissue between the gastric tubules is increased in amount, and the tubules themselves become atrophied. The stomach is sometimes found very small, in other cases much dilated. The milder cases can often be cured by regulating the diet and life of the patient, without much resort to medical treatment. In the severer cases, Dr. Delafield recommends the daily use of the stomach-pump; he advises throwing in about six ounces of tepid water, and then reversing the action, repeating this till the water comes out quite clear, without any fragments. Adult stomachs will hold about twenty-five ounces; more than this gives distress. The best time for washing out is the hour at which the patient has been accustomed to have his attacks of vomiting. Two cases are given in illustration.

Where the small intestine is affected, the chief symptom is pain, referred to any part of the abdominal cavity—a constant dull pain, not like colic; it occurs when the stomach is full or empty, whether the food be spare and simple, or abundant and rich. The use of liquor will usually stop it for a short time. Sometimes it comes on at a particular time of the day. There may be nausea, but not vomiting. The nausea is apt to occur in the morning. The bowels may continue to act with perfect regularity. The appetite is often good. Flatulence is common, but not constant. The patients are up and about, and able to attend to their business, but feel languid and good for nothing. The drugs usually indicated are cubebs, ipecacuanha, and assafoetida. Of cubebs, ten grains of the powder, or twenty minims of the tincture, are to be given three or four times a day. Ipecacuanha is given at first in small doses—one-eighth of a grain, and then increased gradually up to one to four grains three times a day; assafoetida in four-grain sugar-coated pills, or as pilula galbani composita. Horse-exercise is often useful. Walking seldom does good. Travelling from place to place is often of service, if carried through many months.

Dyspepsia due to the liver may be clinically divided, says Dr. Delafield, into two classes. In the first class are the florid, stout, and muscular; in the second, the pallid, spare, and feeble. In the first class, the patients seem to be well nourished, but not to get rid of the excrementitious portions of food, etc. In the second, the patient is imperfectly nourished. In one case, the tissues are over-manured, but badly drained; in the other they are well enough drained, but not manured at all. In patients belonging to the second class, flatulence, headache, queer nervous feelings, hypochondriasis, irregular heart, shoulder-tip pain, constipation, and oxaluria, or even phosphaturia, are all common symptoms. In the treatment, a full and nutritious, but carefully regulated diet, with wines, ales, or spirits, in many cases, and even cream and cod-liver oil, may be of use. Strychnia, aloes, sulphate of magnesia and rhubarb, and podophyllin, may all be of service to relieve the constipation. Bromide of potassium, assafoetida, and guarana, are useful for the nervous symptoms. Above all, mineral acids are recommended. Exercise

should be taken in the open air; in young persons, cold bathing should be used. These cases may be mistaken for congestion of the brain, paraplegia, uterine disease, heart-disease, and even phthisis by careless or inexperienced practitioners. Liver dyspeptics of the other class are often rosy, live well, drink, and use tobacco freely. Indeed, they often take a good deal of exercise. They have, however, similar depression of spirits and hypochondriasis—less headache, but more vertigo—sometimes this may go on to loss of consciousness. The appetite is usually good. The bowels are either constipated or regular. There is often diarrhoea from slight causes. The urine is very apt to contain excess of uric acid or urates. They are often greatly relieved, even for days, by purgatives. The elements of successful treatment are—first, entire absence of every kind of alcoholic drink. Tobacco should be entirely prohibited. Active exercise is required, and sometimes even violent gymnastics. The natural alkaline and sulphur waters often benefit them greatly.

In dyspepsia due to the large intestine, the chief symptom is constipation. It is most common in old people. There may be slight diarrhoea; colic is often present. The patient is much prostrated, vomits his food, and may even take to bed. But opiates only do harm in the long run. A mild laxative, such as the ordinary dinner pill, often relieves at once. In more severe cases, there is often great loss of strength. Nothing relieves the constipation, although the patients often get a number of liquid stools. The state of the rectum should be learnt in such cases by a digital examination. If the rectum be found full, it must be emptied by the scoop, or repeated washing out. The patient should now be watched carefully to see that fæces do not accumulate. Aloes and strychnine are often of service in these cases, to assist the action of the large intestines.

In all cases of dyspepsia, the symptoms should be analysed, and an attempt made to refer them to the different viscera to which they belong.

[The reporter thinks especial interest attaches itself to this paper on dyspepsia, as, rightly or wrongly, a belief exists in England that our American cousins, although not enjoying a monopoly of dyspepsia, still far exceed us in the number and frequency of the disorders of digestion prevalent among them. The forms sketched above are, however, familiar to English readers, and the use of the stomach-pump in the cases described has also been practised in England, France, and Germany for some years, in special cases. It will be seen, however, that Dr. Delafield advises the daily use of the instrument, and gives two successful cases in illustration. The reporter fully believes that cubebs deserves to be used more than it is, in the class of cases described as due to disorders of the small intestine.—*Rep.*]

W. BATHURST WOODMAN.

BERTALOT ON TUBERCULAR MENINGITIS IN CHILDREN.

Dr. H. Bertalot, of Pfeddersheim (*Fahrbuch für Kinderheilkunde*, Band ix. Heft 3), after an interesting account of the early literature of the disease, relates his experience of twenty-four cases distributed over a period of fifteen years, and comprising those only in which a *post mortem* examination was made.

Fourteen were boys, ten were girls. Two cases oc-

curred in the first year of life, seven in the second, five in the third, three in the fourth, three in the twelfth, and one each in the fifth, ninth, tenth, and fourteenth years. The youngest patient was ten weeks old. Twenty-two out of the twenty-four were attacked between November and the end of June. The children were all more or less delicate, they had frequently grown up under bad hygienic conditions, and were generally scrofulous or scrofulo-rhachitic. In twelve there was a distinct hereditary predisposition to tuberculosis; two cases supervened upon chronic coxitis; one upon traumatic erysipelas; two upon pertussis; one upon measles; and one upon the first signs of dentition.

The prodromal symptoms were very various and were often absent; the most constant was wasting. This appeared early, was very gradual in its progress, and was unaccompanied by fever. It frequently spared the face. The other symptoms were pallor, dulness about the eyes, altered expression, indifference to games, depression, diminished or irregular appetite, and alternately relaxed and constipated bowels. The symptoms, in short, were those of the cause of the disease rather than those of the disease itself. Not unfrequently, however, others of a more suspicious character presented themselves in this stage—such as sleepiness, frequently recurring headaches, restless nights with half-opened eyes, terrifying dreams and grinding of teeth. Photophobia appeared but rarely at this period. Older children appeared to be giddy, their gait was unsteady, and they were very forgetful and abstracted.

The symptoms of the disease proper were very differently grouped. Every case had its peculiarities. In many complete, though transient, remissions occurred. The statement of Legendre that cases in which marked pulmonary phthisis has long existed run a very irregular course, was confirmed in only one of the three cases in which this condition was present. Vomiting was absent in only two cases; it varied much, however, in duration and frequency. Most commonly, it occurred once or twice a day. It was rarely repeated after having once ceased for any time, though in one case, after a cessation lasting some days, it reappeared, then ceased once more, and, after a shorter interval, again presented itself. It was accomplished as a rule without exertion, and was unaccompanied by nausea; its immediate cause was usually either sudden change of position or the ingestion of food. Constipation was present in twenty; it generally persisted to the end, and was sometimes very obstinate. In two cases diarrhoea was present throughout; in one of these the bowel was ulcerated (this condition in two others was quite latent); in the other no cause could be discovered. In the remaining two the symptoms began with diarrhoea, though this afterwards gave place to obstinate constipation. Retraction of the abdomen was present in all but three, and in them its form was unchanged. The walls were flaccid in all. Abdominal pain was not common, and in the three cases that were complicated with ulcerated intestines was not noted at all. The tongue, at the commencement, was commonly moist and clean, only in a few cases showing a thick white coating of varying extent; it did not become dry till near the end of the disease. Foul breath, when present, was always a late symptom.

Fever was always present, and in the majority from

the beginning. The temperature never exceeded 103.1° Fahr. On the approach of death it either remained unaltered or showed a gradual rise or fall, though sometimes this was more sudden; thus, in one case it rose rapidly 3.6°, in another it fell to the same extent. The extremities were often cold while the face was burning. The pulse at first was, as a rule frequent; later, except in three of the cases, it became slow and was irritable and remarkably irregular in force, frequency, and intermittence; in one only was the intermission at every third beat. In five, it was cord-like. As death approached it became more frequent in all, and at last often uncountable; at this period also it usually grew regular, or nearly so, and was both smaller and weaker. The skin was nearly always dry, though towards the end of the disease it frequently showed a tendency to become moist. Flushings of the usually pale face were remarkably constant, and were considered of more importance than the *taches cérébrales*, which, indeed, do not appear to have been noted. The eruption described by Forney was partially present in one. Cerebral breathing was observed in all, but it was never an early symptom. Towards the termination respiration became more laboured, and in many cases both more frequent and more superficial.

Headache, either continuous or remittent, and usually frontal, was a very common, and, as a rule, an early symptom. It was entirely absent only in one case. The almost characteristic shriek, to which it probably gives rise, occurred at longer intervals as consciousness began to fade.

Psychical symptoms were never entirely absent; but, in the pronounced form, they were rarely sufficiently early to assist diagnosis. Delirium was most frequent in the older children; in only two cases did it equal in intensity that of purulent meningitis; in the others it was of the muttering variety. As the disease advanced the delirium gradually gave place to somnolence, which, in its turn, passed into coma. This last never appeared suddenly, and when once developed never entirely retroceded, though transient remissions occurred in two cases. General convulsions were, as a rule, late; partial convulsions, involving especially the facial, masticatory, and ocular muscles, early. Trembling, especially of the upper extremities, was slight in the early stage, severe in the later. Strabismus was observed in nearly all—in one as early as the tenth day before death; it was apt to vary in degree, and was most marked on waking the patient. Spastic contractions were commonest in the thumb, which was then forced into the palm; more rarely some of the joints were rigidly flexed. Nuchal contraction, which occasionally passed into opisthotonos, was present in the majority; at the earliest, however, seven days before death. As the disease advanced, the convulsions became both more general and more frequent, and were repeatedly observed to be unilateral. Paralysis, as a rule, was late; the earliest forms were ptosis and strabismus; and in one case the movements of the tongue were affected so that speech became indistinct, and finally unintelligible. Retention of urine was present in three. Incontinence was frequent towards the close. Photophobia, present in some at the beginning, became more marked when the disease was developed, but disappeared with the supervention of coma. Dilatation of one or both pupils then set in. This, however, was in some an early symptom, while in others it was absent throughout. Occa-

sionally contraction followed dilatation. Sluggishness of action existed usually in proportion to the size of the pupil. Oscillation of the eyeballs was never met with. The author took a good deal of trouble with the ophthalmoscope, but never detected either enlargement of the papilla or choroideal tubercles. Hearing appeared to be present almost to the last. The duration of the disease, as nearly as could be made out, was commonly from two to three weeks.

The chief points of importance revealed by the necropsies were that, in twenty-two, other organs were affected; in twenty the bronchial glands were cheesy—one of these being a child ten weeks old. The ventricles were distended with fluid in all; the quantity varying from two to four ounces. Tubercles of the convexity were present in only two cases, and then but scantily. They were never found in the brain-substance; but in three cases tubercular tumours existed, one of which was as large as a walnut. Softening of the stomach was present in three cases. The treatment, which was chiefly locally antiphlogistic, at most, moderated for a time some of the symptoms.

RALPH W. LEFTWICH, M.D.

CROTHERS ON INEBRIETY.

In an article in the *Philadelphia Medical and Surgical Reporter* for June 10, entitled 'Clinical Studies of Inebriety,' Dr. T. D. Crothers, Assistant Superintendent of the New York State Inebriate Asylum, Binghamton, writes as follows. Inebriety exceeds all other affections in its mortality and influence over the physical and mental conditions of life. No other disease is so certainly transmitted, entailing on the future deterioration and final extinction of the race. It is defined as a cerebro-psychical disorder of the nervous system, of the same genera and group of neuroses as that of loco-motor ataxy, progressive muscular atrophy, typho-mania, syphilitic insanity, and many forms of epilepsy. It seems to follow our peculiar civilisation, keeping pace with its industrial activities, and its fierce struggles for wealth and power. It may often be traced in storm-like waves through the changes of political life, the ebb and flow of emigration, and the speculations and social convulsions of the times. The history of inebriety, as a disease, is a repetition of every advance in new fields of medicine. Recognised in the second century of the Christian era by Ulpian, the great Roman jurist, in his digest of laws, it was, eleven centuries later, during the reign of Alonzo the Ninth, of Spain, studied and treated by the State as an affection requiring special laws and management. Three centuries further down, many of the German States endorsed these views, and enacted laws based on them. Then came the observations of Dr. Rush, in America; Professor Platner, of Leipzig, in 1809; and Salvator, of Moscow, in 1817, and many others, who boldly advocated that inebriety was a disease, and could only be reached by special means. From this time down, during the last fifty years, this subject has been agitated by all classes. Although facts, statistics, and observation amply prove that inebriety is a disease of the physical and mental organism, yet the profession are slow to recognise it, wavering between the positive denials of some specialist and the empiric theories of temperance

societies, who believe it a vice. We propose to show, from the clinical study of cases treated at this asylum, that inebriety is both a physical and a mental disorder, at all times and in all cases. However obscure its origin may be, it has always a starting point, in perverted function or disordered cell-growth, and its progress is influenced by definite conditions, and its termination in death or recovery is as fixed and positive as pneumonia or tuberculosis. The following cases bring out prominently the evidence of disease, beyond all power of the patient to check or control.

CASE I. Inebriety proceeding from Physical Lesion arising from Syphilis.—H. B., a merchant, the head of a large, prosperous house, temperate, and in good health, regular in his habits, contracted syphilis in 1859. He had buboes and a slight fever, from which he recovered in a month or more, and resumed business as usual. Two months later he was seized with intense depression, from no cause, and a strong desire for stimulants; this became so intense that he drank freely, and with much satisfaction. In two days it passed away, and three months later returned, more depressing, and could only be satisfied in a similar way. From this time on these paroxysms for liquor, preceded by depression, increased in intensity and frequency. He was examined and treated by eminent physicians, without avail, and all effort on his part to resist and break up this desire was useless. In 1866 these attacks had grown to such an extent that he was incapable of business, suffering at least one week every month or more. He accordingly went to Europe, seeking every means to break up this craving, with but little relief. In 1870 he went back to Europe with his family, visiting Egypt, India, and making long sea-voyages, returning after three years, much improved, the paroxysms only returning at long intervals. His health was good, and his mind clear. Two years later he gave up his business and came here for treatment. The periods of drinking had increased to one every month, lasting from four to eight days, marked by excessive drinking of brandy or alcohol. His health was very much reduced, and incipient *delirium tremens* had appeared. The interval of sobriety was spent in anxious efforts to repair and recover from the effects.

There was no trace of inherited insanity or inebriety in this case. The taste of liquor was unpleasant, and only its effects would drive away its nauseating odours. The desire to drink came on without premonition, and he seemed forced to give way to impulses that his reason denounced. For fifteen years he sought earnestly and faithfully to break away, but failed. The origin here came clearly from the syphilis. This poison producing some lesion of the brain-cells, was manifested in the diseased craving at certain times. Possibly no pathological search could have shown the exact lesion, or revealed any structural changes, but strong diseased impulse existed, from which the patient could not recover.

CASE II. Inebriety from Physical Lesion, beginning in Concussion of the Brain.—B. A., a lawyer, liberally educated, of strong intellect, and temperate, entered the South-western army, as an officer, in 1860. After a few months of active service, he was sent to the hospital, with a severe attack of typhoid pneumonia, attended with much delirium. He recovered after three months of illness, and, after a long furlough, in which he regained all his further strength, he entered the army of the Potomac, in 1862, and while

leading his command at Chancellorville, was made unconscious by the explosion of a shell. Taken back to the hospital, he was found to have no external injury, but to be suffering from concussion of the brain. Active delirium came on, and continued for twenty-one days, after which reason returned, and this period was all a blank to him. He resumed his command, and continued until the close of the war, receiving no injury, and in apparently good health. He had been a strong temperance man from principle, and up to the time of receiving this concussion he had scarcely tasted liquor. Soon after resuming duty he was seized with uncontrollable longings for stimulants, at distinct intervals. This he gratified, with inward satisfaction (privately), during the war. Sometimes two days' or more drinking would only satisfy him. The war over, a return to his profession brought increased longings and periods of gratification. Every means was tried to break up this desire; the taste for liquor was unpleasant, but he was impelled, against all reason, to seek this relief. Chagrined at his weakness, he grew morose and more irritable, would retire to his room when drinking, and become destructive if interfered with. Eating nothing, and in a condition of delirium, followed by a day or more of stupidity, the paroxysm would end in weeks of prostration or fever. This struggle continued until 1869, when, after a sojourn at one of the mineral springs of the South, he resolved to give up, and put himself under an attendant, who would watch over and sustain him. He was in better health, and succeeded in abstaining for two years, although the desire came on at intervals. A dull, wandering pain, called rheumatic, came and went; he noticed, also, in bad weather and changes of the moon, that he felt worse. At these times the attendant would watch with him, using all means to divert his mind and build up the body. In 1871 he received the sudden news of the death of a brother, and unconsciously he began to drink again, and only after a week did he realise his situation. From this time on his course was one of protracted and severe paroxysms of drinking, the intervals growing shorter, and the cutaneous sensations becoming more and more perverted. *Delirium tremens*, in a slight form, appeared, memory failed, and rheumatic pains increased. Fatigue or excitement on any unusual circumstance provoked a return of the drinking.

No inherited drunkenness or insanity could be traced in this case. No physical or mental weakness existed until after exposure in the army. The desire for liquor all began after the concussion at Chancellorville. The severity of the injury was apparent in the long time of unconsciousness, and the sequel indicated a profound cerebral disturbance, manifested in uncontrollable inebriety.

CASE III. *Inebriety from some Mental Lesion, followed by Unconscious Paroxysms of Drinking.*—T. H., a baker, of common-school education, of vigorous health, and temperate, a man of wealth and large social and business relations, in 1860 was elected to a prominent office in his native city, requiring great care and responsibility, and frequent visits from home, subject to irregularities and excitements, during which he drank wine moderately. Two years later, at the age of fifty, he drank brandy to excess, impulsively, and without any reason. This came upon him suddenly, and in two or three months a similar paroxysm followed. Retiring from public life and travelling for some months made no difference. These periods were preceded by moroseness and

irritability, and sensations of cold, which he did not realise as premonitory of inebriety. Then he would rush out for liquor, and after one glass all memory of events ceased, and he would wake up after the attack as from a sleep. These periods lasted from a few hours to many days. In 1868 he was brought to this asylum, and went away very much improved after six months' treatment. Three years later he relapsed, and drank excessively, from grief for the loss of some friends, and then continued at variable intervals to drink as before. He was seized with *delirium tremens* on one or two occasions, and made many efforts to recover, without avail. He seemed strangely unconscious of the approach of these attacks, and demented and oblivious to all things after the drinking began. His father was a temperate man up to fifty years of age, then drank to excess, and died a few years later, a drunkard. His grandfather began to drink late in life, and died from its effects.

The peculiar unconsciousness which began at the moment of taking liquor indicated a profound mental disturbance, controlling the entire organism. The predisposition to drink late in life was inherited direct, and appeared to be most intense at fifty years of age. His peculiar circumstances and position in life, at this time, favoured the return of inebriety transmitted from his father. The progress of the case indicated that the presence or absence of certain exciting causes, of both a physical and a psychical origin, largely controlled it.

CASE IV. *Inebriety from Inheritance and Weakened Mental and Physical Powers.*—S. H., a dentist, educated, twenty-six years of age, has been a spasmodic drinker for eleven years. He began during the excitement and triumphs of college life. He had a strong love for liquor, which increased yearly. For the first three or four years he only drank after fatigue or excitement, and not often to intoxication. Later he had spasms of drinking, depending on various exciting causes. During the last four years he has drank alcohol pure, and in all its forms, with absinthe, etc. He has had *delirium tremens* slightly, and convulsions of epileptic character. He is pale, anæmic, and has disordered sensations of heat and cold; is restless, sensitive, and anxious to save himself from this affection. He has no control of his will when he begins to drink. The sight of a bottle, or bar where liquor is sold, will rouse up intense cravings for drink. He has adopted various means to keep away from this temptation. Sometimes he succeeds in abstaining for three or four weeks. He has been unconscious of his drinking during the period, for two years past. He has shown suicidal tendencies, is reckless and quarrelsome, and has premonitory symptoms, such as wildness of the eyes, confused, uneasy movements, before drinking. His father drank wine after meals, and was a morose, passionate man. His mother was a strong, impulsive woman, who alternated between the extreme of exaltation and depression. His grandfather, on his mother's side, was demented, and several of his children were feeble-minded, eccentric persons.

This was a case of well-marked insane diathesis, inherited, skipping one generation, and appearing as impulsive inebriety. The tendency to mania, in some of its obscure forms, was determined by the moderate drinking habits of father and mother, to alcoholism. The early excitement of college life was the starting-point. Cerebral disorganisation had gone on to such an extent, that the least exciting

cause provoked its appearance. No reason or will-power had any influence over these paroxysms.

These cases are presented because they illustrate causes that are not recognised in every instance, particularly when presented in private practice. Knowing the exciting causes, with the conditions and surroundings of the patient, the prognosis of inebriety could be certainly made out before the victim is comparatively powerless to help himself. No society, with moral and social influence, can aid him; nothing but the restraint of an asylum and watchful care, with special treatment, will avail. These cases reveal a degree of mental and physical disorder which cannot be termed by any other name but disease. There are evidently tissue-degenerations and lowered vitality, with perverted mental action, to begin with, and the use of alcohol has precipitated cell-disorganisation, bringing on a storm of morbid impulses, that sweeps away all reason and will-power, and paves the way for a return. The system, from various causes, takes on favourable conditions for inebriety, and this affection follows as a sequence. From the first attack, new conditions of debility begin, dependent on the alcohol taken, and a chronic stage speedily follows. The practical end to be sought is, to distinguish those early causes, and guard against them; and when these are overlooked, and the affection begun, a careful study of them will indicate much of the future treatment essential to final recovery.

PEASLEE ON INCISION AND DISCISSION OF THE CERVIX UTERI.

At a meeting of the New York Academy of Medicine on June 1, 1876 (*New York Medical Record*, June 24) Dr. E. R. Peaslee read an exhaustive paper upon the above subject, in which he referred to the operation of incision as performed by Simpson, discission as performed by Sims, the operation which he himself performed, and the immediate and remote effect following the three varieties.

By incision was meant simply cutting into the substance of the cervix, while by discission was meant severing the cervix, or cutting through it entirely.

Dr. Peaslee employed the general term trachelotomy, and under that head considered the methods, the uses, the abuses, and the true value of the operation, and then explained his own method, which he believed not to be liable to the objections applicable to the operation as originated by Simpson and Sims.

As long as trachelotomy must be recognised in the treatment of stenosis of the cervix uteri, the least objectionable method, of course, should be preferred. The two methods authoritatively practised were: 1, Simpson's, or deep incision of the cervix; 2, Sims's, or discission of the cervix; and 3, he added the superficial incision of the cervix, or his own operation.

Simpson's Operation.—Sir J. F. Simpson, believing that the stenosis was most commonly found at the internal os, devised a metrotome, with which he made incisions for its removal. Dr. Greenhalgh subsequently devised an instrument for the same purpose, which was regarded as more perfect than Simpson's, because it cut more symmetrically, but at the same time cut more extensively, which was decidedly objectionable. Simpson's operation became very common, but Greenhalgh's instrument had generally been preferred. Indeed the operation

became so common that, at last, it had been resorted to where no stricture was present.

Dr. Peaslee then proceeded to consider the immediate and remote effects of the incision of the cervix uteri, and it was maintained that by the operation the shape, size, and normal relations of the cavity of the cervix to the cavity of the body were at once changed. In some cases fatal, and, in many, profuse hæmorrhage had occurred; in others pelvic cellulitis and septic peritonitis had been developed, which had proved fatal. Dr. Peaslee was surprised that such results had not followed the operation far more frequently. For, by the use of Greenhalgh's instrument, when the small incision was made, the wall of the cervix was cut more than one-half through upon both sides, while the large incision went so near through into the peritoneal cavity, that the least inclination of the uterus or the instrument, or a less thickness of the cervical wall than normal, would permit the blade to cut entirely through with the greatest ease.

In all cases in which the operation had been fully resorted to, the form and size of the entire uterine cavity, both corporeal and cervical portion, had been entirely changed, and instead of being of the shape of a flattened hour-glass, the constricted point at the internal os, it had been made bottle-shaped, with the bottom of the bottle knocked out.

Such a cavity might receive menstrual fluid from above, and seminal fluid from below, but it could not retain either. According to Sims, said Dr. Peaslee, the operation cuts altogether too extensively, but the same objection, it was maintained, also held good against Dr. Sims's operation. The immediate dangers, therefore, were hæmorrhage, pelvic cellulitis, and septic peritonitis. No statistics concerning the immediate effects had been published, as they should have been.

Dr. Peaslee then noted Barnes's objection to Greenhalgh's instrument, and also cited the history of a case in which Simpson had performed his operation for the cure of sterility, when stenosis or displacement was not present, and a nearly fatal hæmorrhage ensued.

But the remote effects of the operation were not to be overlooked. Admitting that dysmenorrhœa was dependent upon stenosis, what could be expected in the way of utero-gestation with an uterus that had thus been maimed? The seminal fluid could not be retained, and should conception accidentally take place, gestation would be brought to an end prematurely. The operation was seldom followed by conception, Dr. Peaslee maintained; but when it did occur, abortion was the rule. And if closure of the wound occurred, the woman was not so well off as before the operation, because more or less induration would follow and might increase; and although the dysmenorrhœa might be relieved, the probability of conception and utero-gestation to the end of term was diminished. Sims had objected to the operation because eversion of the labia uteri followed; but it was claimed that the same objection held good against his own operation.

With reference to the uses of the deep incision, it could not be recommended for sterility, since it often prevented conception and favoured abortion. It, however, relieved, and might cure dysmenorrhœa, if dependent upon obstruction; though the tendency, if the wound closed, was to increase the very condition for the relief of which the operation was performed.

Dr. Peaslee rejected the operation for the relief of

dysmenorrhœa even when depending on stenosis, and condemned the metrotome of Greenhalgh altogether. Simpson's instrument might be useful for making incisions in the cervix to aid the removal of uterine fibroids, but under no other circumstances would he recommend it.

Sims's Operation.—Attention was next turned to discission of the cervix uteri, or Sims's operation. It was first practised in January, 1857, and consisted in completely severing with scissors the wall of the cervix, upon both sides, up to the vaginal junction, after which a narrow-bladed knife was introduced into the cavity of the uterus, and the internal os divided, as thought necessary, and the opening through the canal enlarged, which had remained intact after using the scissors. Dr. Peaslee argued that by Sims's operation the cervix was annihilated for all practical purposes, and that the shape and size and value of the uterine cavity was usually destroyed. The immediate effects, therefore, of the operation, were change in the form and size of the uterine canal, frequently alarming hæmorrhage, sometimes pelvic cellulitis, and septic peritonitis, which was almost invariably fatal when it occurred. The fact that the cervix was severed completely to the vaginal junction rendered the operation more dangerous, as far as hæmorrhage was concerned, than Simpson's. Dr. Peaslee had known of four cases in which fatal hæmorrhage followed Sims's operation, and believed that cellulitis and peritonitis were much more likely to follow Sims's than Simpson's, because of the greater surface afforded for the absorption of any septic material. The doctor believed that, if all the fatal cases which had followed the operation had been published, the list would be startling, and it would hardly seem necessary to state that the life of the patient should not be thus jeopardised without the greatest necessity. Yet the history of two cases was selected in which the operation had been performed; but why, Dr. Peaslee was unable to tell. For, in the first instance, the woman was a maiden lady over fifty years of age, had never had dysmenorrhœa, and it was scarcely possible that it could have been done for the relief of sterility. In the second case, there was no dysmenorrhœa or constriction of the cervical canal, and it could hardly have been done for the relief of sterility, because the woman had been married only five months.

Such facts could be explained only upon the ground of a mania which practitioners sometimes had for performing special operations. The change produced by Sims's operation, it was believed, would usually relieve the dysmenorrhœa if dependent upon constriction, but it would probably prevent conception, and, if impregnation should take place, abortion would almost certainly follow. Dr. Peaslee maintained that, when such complete incisions through the cervical wall were made, they should be treated the same as rupture of the cervix in parturition, and closed as soon as possible. It was remarked that discission had been performed for the cure of flexions of the uterus; but such an operation for such a purpose was regarded as something like dividing the sphincter ani muscle for the sake of affording relief to a constriction in the sigmoid flexure of the colon. Such an operation could do nothing for the relief of a flexion except to relieve the congestion, and that would be much more safely accomplished by the application of a half-dozen leeches.

Dr. Peaslee referred to the sagittal incision recommended by Sims for ante flexion, and endorsed by Barnes. It was performed by dragging the posterior wall of the cervix as low down as possible, and then slitting it up to the vaginal junction, after which a narrow knife was passed into the canal and an incision made, so as to bring the cut exactly in a line with the axis of the cavity of the uterus.

If that could accomplish all it promised, there was a better way to bring it about, said Dr. Peaslee; and he then added that the operation in ante flexion was impossible; it never had been and never could be performed. There was also an unsurmountable objection to the performance of the operation for displacement; since, even if it could be accomplished, it ignored the very first indication in the treatment of all displacements, viz. to restore the uterus to its normal position. An incision made in the manner referred to, for the purpose of replacing a uterus, first of all left it in its malposition. But the operation did not effect what had been proposed, because in that condition of the uterus its performance was absolutely impossible. For the axis of the cavity of the cervix met the axis of the cavity of the body at an angle of 165° , and a continuation of the line of the axis of the cavity of the body would bring it through the cervical wall nearly to the vaginal junction when the uterus was in its normal position.

Now let the body of the uterus fall forward a little, and it was found that the line of the incision, being a continuation of the axis of the cavity of the body, went through into the peritoneal cavity. In the second and third degrees of ante flexion the line would not enter the vagina at all; but, on the contrary, in the third degree at least, would fall pretty well towards the woman's umbilicus.

In all cases of flexion or curvature of the cervix the operation could be performed, but that was an entirely different state of affairs, and for their relief the operation was a proper one. It should, therefore, be restricted to such cases of curvature and flexion, and never attempted in cases of ante flexion; for, in the latter condition, it never had been and never could be performed.

Dr. Peaslee then referred to the diagrams which had appeared in nearly every work published upon diseases of women within the past ten years, and had passed unchallenged. (They can be found in the last edition of Thomas's work on "Diseases of Women," at pages 412 and 413.) From his study of the operation, he had come to regard them as visionary and fallacious.

With regard, then, to discission as a means of cure for sterility and dysmenorrhœa, Dr. Peaslee rejected it; and farther, knew of no condition in which it could be recommended, unless it was employed to assist in the removal of fibroids; and then the unilateral incision was, as a rule, all that was required. No statistics regarding the success of Sims's operation for the cure of sterility alone had been published.

1. Deep incision and complete discission of the cervix uteri were attended by certain immediate dangers, and were productive of certain remote consequences prejudicial to the child-bearing function of the woman. Of those there were profuse, perhaps fatal, hæmorrhage, pelvic cellulitis, septic peritonitis, sterility, and abortion.

2. Those risks and effects were all due to the extensive division of the walls of the cervix, and the consequent enlargement of its cavity; and with the

sole compensation of relieving the symptoms or curing dysmenorrhœa, if dependent upon stenosis.

The question then arose, could such extensive division be so far avoided as to avoid these risks and at the same time remove the condition that predisposed to sterility and dysmenorrhœa?

To answer the question properly, it became necessary to study the calibre of the cervical canal, and determine the size necessary to relieve the dysmenorrhœa and favour conception.

It was laid down that the normal cervical canal in the imparous woman was one-seventh of an inch in diameter at the internal os, and one-fifth of an inch in diameter at the external os. The larger size of the external os had reference to conception, and had no special influence against dysmenorrhœa, since the menstrual fluid after passing through the internal os could be conveyed to the vagina without difficulty through a canal of the same size.

In the parous woman, the internal os remained nearly twice as large as in the imparous, and was about one-fifth of an inch in diameter, while the external os was increased in size in nearly the same ratio, and was three-tenths of an inch in diameter.

If, therefore, an internal and external os existed of these sizes, the woman would be insured against sterility and dysmenorrhœa. Now, to obtain that size required an incision only one-thirtieth of an inch in each direction at the internal os and one-twentieth of an inch at the external os, to convert the ora of the virgin into the ora of the parous woman. Practically, it was believed to be well in some cases to make the incision deeper, but if there was no congestion, the depth of the incision noted was regarded as sufficient. Now, to secure the required calibre of the cervical canal and internal os, Dr. Peaslee, in cases where the stenosis was slight and the cervical canal soft and pliable, had been in the habit of employing a series of steel conical dilators. But about ten years ago he had devised a measure which was more prompt and less painful than dilatation, and less dangerous than either Simpson's or Sims's operation. The operation consisted in making a superficial incision; it had for its direct object the removal of the stenosis of the cervical canal, and nothing else, and the rules which governed its adoption were embraced in the following propositions.

First, with reference to the 'internal os.'

1. If a sound one-fifth of an inch in diameter passed easily, there was no stenosis, hence no incision was required. One-fifth of an inch in diameter was the size of Dr. Peaslee's largest conical dilator and his large sound.

2. If a sound one-sixth of an inch in diameter passes, there was no absolute necessity for an incision to relieve the stenosis. But there might be stenosis for the passage of fluid, though not for the passage of a sound; and under such circumstances an incision might be required.

3. If a sound one-seventh of an inch in diameter passed, and gave no evidence of stenosis, no incision was required.

4. If a sound one-eighth of an inch in diameter could not be passed, there was present either stenosis, or, what was more probable, one of the flexions. Prove, therefore, in every case, before operating for stenosis, that the obstruction at the internal os, to the free passage of the sound, one-eighth of an inch in diameter, or more, was not due to flexion.

Second, with reference to the external os.

5. If a sound one-fifth of an inch in diameter

could be passed, there was no stenosis. But if there was congestion of the lining membrane of the cervical canal, there might be stenosis, practically with reference to conception, and an operation might be required.

6. If the external os admitted a sound only one-sixth of an inch in diameter, there was probably stenosis with regard to conception, and an operation might be necessary.

7. In case the operation was performed, it was important to retain the fusiform shape of the cervical canal as far as possible.

Dr. Peaslee then showed his metrotome for the performance of the operation he described.

The incision should be carried only to such an extent as would give the precise average relations of size found in the cervical canal of the parous woman. In cases complicated by congestion, a larger opening might be required, and the limits might extend beyond one-fifth of an inch in diameter, for the internal os, and perhaps to one-third of an inch for the external os. Dr. Peaslee's operation then consisted mainly in making a superficial incision in the cervical canal, sometimes not extending through the mucous membrane, and sometimes a trifle more, as already indicated. It should be performed at least four days after or six days before the catamenial period; and, by preference, the small blade of Dr. Peaslee's instrument should be used, for the calibre of the canal could be easily increased with the dilators, and by so doing the liability of union of the wound was diminished. No anæsthetic would be required, and the amount of hæmorrhage seldom exceeded two drachms. He had never known of pelvic cellulitis or peritonitis following the operation, because the medullary portion of the cervix had not been disturbed. His observations were based upon about three hundred operations. The woman should be kept in bed for two or three days, and not permitted to walk for a week.

Sometimes it might be necessary to repeat the operation; but, in all the cases where he had been obliged to repeat it, Simpson's or Sims's operation had previously been performed, and the incision had closed. In such cases, the cicatricial tissue was so firm, that repetition of the incision usually became necessary. Nor had the operation been followed by sterility or miscarriages, as had the other operations, and it had very often cured the sterility, and the dysmenorrhœa of stenosis. It was, therefore, an operation that proposed all the advantages of the others, and without their dangers. In conclusion, Dr. Peaslee suggested that both Simpson's and Sims's operation should be rejected for the treatment of sterility and dysmenorrhœa, and that some better method should be employed, of which, perhaps, his own was merely a forerunner.

In the discussion which followed the reading of Dr. Peaslee's paper, Dr. Fordyce Barker remarked that he believed it to be high time that the subject under consideration was discussed, and that the opinions and practices of the leading gynecologists of the city should be known and understood. He argued that it would doubtless relieve the profession from some reproach, and vindicate it from a dangerous under-current of belief, that the leading practitioners of the city of New York regarded slitting open the cervix uteri as the grand panacea for all uterine disease, not only for the cure of local troubles, but formed a therapeutical measure for the cure of hysterics, nymphomania, and all allied maladies.

In certain cases, doubtless the operation was required, but as a general thing it was not necessary. About twenty years ago Simpson presented a hysterotomy to Dr. Barker, and the first two operations he performed were followed by conception, and the children were carried to term. The next twelve cases were cured of the dysmenorrhœa, but the sterility remained. Since that time the doctor had closely watched professional opinion with reference to the operation, and had also seen patients in an extremely dangerous condition from loss of blood following the operation; and his experience enabled him to verify the correctness of some of the statements made by Dr. Peaslee with reference to the unnecessary performance of the operation.

The operation should never be performed except for stenosis, either congenital or acquired. Acquired stenosis might come from displacement; but there were many cases of displacement which were not attended by either sterility or dysmenorrhœa. Many such patients, however, had been treated for displacement, when no treatment whatever had been necessary. The doctor then related a case, and the woman had had three or four miscarriages since the performance of the operation. Dr. Barker remarked, in conclusion, that he had not performed the operation in a single instance in all his hospital practice, but that he had occasionally performed it in private practice.

Dr. Emmet coincided with the general doctrine advanced in the paper, and also in the remarks made by Dr. Barker, adhering, however, to the view that the operation of discission was proper in cases of flexure and curvature of the cervix.

Dr. Pallen was inclined to the opinion that the operation was justifiable, and much more frequently called for than one might be led to infer from the paper by Dr. Peaslee.

ANATOMY AND PHYSIOLOGY.

LÉPINE ON THE INFLUENCE OF THE EXCITATION OF THE BRAIN ON THE BEATS OF THE HEART.—Lépine (*Gazette des Hôpitaux*, no. 90, 1875) found that stimulation of the surface of the most anterior part of the cerebrum influenced the heart-beats of the dog. If the *left* vagus were divided in a curarised dog, and the *right* surface of the brain were stimulated, the number of heart-beats was unchanged; if the *left* side, on the contrary were stimulated, the number of heart-beats was diminished and the height of the pulse sank.

ROCHEFONTAINE ON THE PHENOMENA PRODUCED BY FARADISATION OF THE CORTEX OF THE BRAIN.—Rochefontaine (*Gazette Médicale de Paris*, no. 52, 1875) found when both vagi were left intact, and the superior cervical ganglia of the sympathetic of the dog were removed, that by faradisation of the superior frontal convolution before and behind the sulcus cruciatus, there was an increase of the blood-pressure and the heart-beats. If, however, the superior cervical ganglia were left intact, and the vagi divided between the base of the skull and the nerve-fibres passing from the superior cervical ganglia to them, then, on stimulating the same points on the surface of the brain, there was a very considerable diminution of the blood-pressure and of the heart-beats. Stimulation of several parts of the

surface of the brain had, therefore, the same effect as stimulation of the depressor nerve. In a similar manner, from four different parts of the surface of the brain, contraction of the spleen was produced; from other points contraction of the intestines. The author concludes from this and from the analogy of the phenomena obtained on stimulation of peripheral sensory nerves, that an unlimited number of sensory points exist on the surface of the brain, whose stimulation acts on the terminations of cerebral centripetal fibres. These conduct the impression to the nuclei of grey matter in the intracranial portion of the cord, whence it is transferred to centrifugal nerves to produce these various phenomena.

As supporting his view the author cites the experiments of Brown-Séquard, who, by the application of the actual cautery to the centres placed in the cortex, did not succeed in causing movements of the extremities.

FISCHER ON THE THERAPEUTIC GALVANISATION OF THE SYMPATHETIC.—G. Fischer (*Deutsch. Arch. für Klin. Med.* Band xvii. p. 1, and *Centralblatt für die Medicinischen Wissenschaften*, no. 25, 1876), has made experiments on horses and cats. The first point investigated was, in what manner the blood-pressure in the arteries supplied by the sympathetic and lying outside the cranium was influenced by electrical stimulation of the cervical sympathetic. The manometer was placed in the internal maxillary artery.

By faradisation of the cervical sympathetic of the horse, the blood-pressure was increased and pronounced tension of the arterial walls was produced, whilst with a constant current only negative results were obtained.

A second series of experiments was performed on cats. In this animal the cervical sympathetic lies in a sheath of connective tissue, along with the vagus and the carotid, and can be easily isolated, without hæmorrhage. With regard to the effect on the contraction of the iris, the result was the following. On passing the faradic stream through the skin, an obvious, but very feeble effect was produced; stimulation of the isolated nerve gave a pronounced reaction. By galvanic stimulation, only closure was observed, sometimes no effect at all; the complete law of contraction could in one experiment only be observed, when the vagus was stimulated simultaneously with the sympathetic.

As to the effect of galvanisation of the sympathetic on the circulation in the brain and its membranes, the author found in eight faradisation experiments on cats, that the brain-pressure was in five cases increased during the passage of the current, in three cases diminished; but all variations, positive as well as negative, were extremely unimportant. By galvanisation in eleven experiments, there was in four only a minimum increase, in three no change; there never was a reaction from the closing or opening shock in the whole series. Galvanisation never had an effect on the frequency of the pulse; faradisation of the vagus increased the blood-pressure; it was slowly increased also by galvanisation, when the current was passing; and by simultaneous faradisation of the vagus and sympathetic in five experiments, the brain-pressure was increased in four, and in two considerably so. By stimulation of the sympathetic on each side, the pressure rose rapidly and considerably, to sink again when the current was passing; and every time, even with the most profound narco-

sis, clonic spasms appeared in the extensors of the hind foot and of the back.

EULENBURG AND LANDOIS ON THERMAL INFLUENCES PROCEEDING FROM THE HEMI-SPHERES OF THE CEREBRUM.—Drs. Eulenburg and Landois (*Centralblatt für die Medicinischen Wissenschaften*, no. 15, 1876), operated on dogs, and they found that young animals were specially well suited for their purpose. The estimation of the temperature was taken thermo-electrically by means of a Meissner-Meyerstein's electro-galvanometer. As thermo-electrical elements, two varnished Dutochet needles were employed. After opening the skull and exposing the surface of the brain, the grey matter was destroyed by means of redhot copper wires to the depth of one to one-and-a-half millimètres. The animals were kept deeply under chloroform. When a certain portion of the brain was to be stimulated the animal was curarised, and induction shocks were applied by means of two fine platinum wires which served as electrodes. The chief results were the following.

1. Destruction of certain regions of the anterior lobes of the brain corresponding to the temporal region caused at once a considerable increase of the temperature in both contra-lateral extremities. The increase of temperature occurred immediately after the complete destruction of the corresponding parts of the surface of the brain, often before the animal awoke from the chloroform, and before it made any spontaneous movement. The increase immediately after the operation may be 5° to 7° Cent., in other cases only $1\frac{1}{2}^{\circ}$ to 2° Cent.

2. The thermal areas for the anterior and posterior extremities are separated from each other. The area for the fore foot lies somewhat more anteriorly, and somewhat external close to the lateral end of the sulcus cruciatus. Destruction of the supra-Sylvian gyrus has no thermal effects.

3. In successful cases, after the animal awakened from the chloroform, there generally was disturbance of motion, and it seems that the portions of the surface of the brain which have this thermal action must lie in the neighbourhood of the corresponding motor areas.

4. The increase of the temperature is in nearly all cases clearly pronounced for a long time after the injury, sometimes even for three weeks; generally, however, it returns to the normal on the second or third day. Localised electrical stimulation of the above areas with sufficiently weak currents is accompanied by a small and temporary diminution of temperature (0.2° to 0.6° Cent.) in the contra-lateral extremities.

The author is of opinion that these facts justify the conclusion that there is a vaso-motor apparatus in the grey matter of the brain, and that it partly represents the central terminations of the vaso-motor nerves which run in the cerebral peduncle.

CARVILLE AND DURET ON THE FUNCTIONS OF THE CEREBRAL HEMISPHERES.—C. Carville and H. Duret write on this subject in the *Archives de Physiologie*, 1875, and there is an abstract in the *Centralblatt für die Medicinischen Wissenschaften*, no. 52. The first part of this very extended research contains an historical review and criticism of the experiments hitherto made on the function of individual parts of the brain. The authors reject entirely, and with justice too, the results of the experi-

ments of Fournié, obtained by injecting chloride of zinc into the brain of the living animal. Even the results of Nothnagel's experiments they discard (injection of dilute chromic acid). The second part of the paper is devoted to an experimental criticism of the results of Hitzig and Ferrier. The idea of Schiff that the movements caused by stimulation of the surface of the brain are reflex, the authors regard as not supported by fact. They cite experiments performed on living and dead brains, to show that on a certain point of the surface of the brain localised currents extend both laterally and in depth. Two platinum needles connected with a very sensitive galvanometer were placed on the surface of the brain, or pushed into it to the depth of several millimètres. On applying weak induction-currents to certain parts of the surface of the brain, the galvanometer needle was more or less deflected. Nevertheless, the localised action of the current is to be assumed, in as far as stimulation of parts of the surface of the brain produces different and quite distinct movements when only weak currents are employed, a fact already sufficiently pointed out by Hitzig. With regard to action of anæsthetics the authors agree on the whole with Hitzig. A further series of experiments is given to show that the integrity of the grey matter is not necessary for the occurrence of circumscribed movements. Similar experiments were performed by Braun and Putnam. The experiments are new which prove that complete extirpation of the corpus striatum does not hinder the occurrence of movements on stimulation of the surface of the brain, and that distinct bundles of the centrum Vieussensii conduct the excitement from the brain to the periphery. Further, some results of Ferrier are corrected, which were obtained by employing too strong a current. The extirpation experiments do not show anything new. The authors come to the conclusion that the cerebral centres are replaced after their destruction in the grey matter of the same hemisphere.

Further experiments are connected with elucidation of the functions of the corpus striatum and optic thalamus. Concerning the latter, the authors confirm the experiments of Ferrier, according to whom electrical stimulation of these structures does not cause either pain or movement. In studying the function of the corpus striatum, one must specially bear in mind the nucleus caudatus and the corpus lenticulare. Electrical stimulation of the nucleus caudatus yielded the author the same results as Ferrier, viz., contraction of all the muscles on the opposite half of the body. Complete extirpation caused a great weakening of the opposite half of the body, (frequently falling to one side) and a movement in a circle, in which the animal always executed the same movements with the sound feet, and rotated around the affected ones like a top. On injuring the internal capsule, complete paralysis of both extremities of the other side is produced. This occurs upon injuring the anterior portion of the first two-thirds, which lies immediately under the ventricular surface of the nucleus caudatus. Section above the same produces only incomplete hemiplegia. Destruction of the posterior part of the capsula interna (between the thalamus opticus and nucleus lenticularis) produces hemi-anæsthesia of the opposite half of the body.

The authors, from their experiments, attempt to locate the probable position of the different centres in the cortex of the brain in man thus. The centres for the different movements of the upper and lower extremities lie in the middle of both upper posterior

cerebral convolutions, in the middle of the anterior cerebral convolutions, and in the whole of the upper temporal lobes.

The centre for the movements of the neck and head lies in the posterior part of the first frontal convolution, where it unites with the anterior central one.

The most probable centre for the muscles of expression and eyelid lie at the place of junction of the second frontal convolution with the anterior cerebral one.

The centres for the movements of the tongue, jaw, and lips are placed in the third frontal convolution (Broca.)

Single centres for the movements of the eye-balls, are placed, according to Ferrier, in the gyrus angularis. The first temporo-sphenoidal convolution has probably a relation to the organ of hearing.

Lastly, the authors give a series of experiments which have a pathological importance. Coma occurs most easily in extensive hæmorrhage into the centrum semi-ovale; perhaps with hæmorrhage on the convexity, and specially of the frontal lobes. If an intraventricular hæmorrhage stimulate the ependyma of the ventricle, tetanic convulsions of the extremities of the opposite sides of the body result. With hæmorrhage at the base stretching towards the medulla, the phenomena of general tetanus are always to be observed at the moment of the attack.

WM. STIRLING, D.Sc., M.D.

FÉRÉ ON SOME POINTS OF THE TOPOGRAPHY OF THE BRAIN.—M. Ch. Féré (*Archives der Physiologie*, Mai-Juin, 1876) says that the brain is so altered by flattening after removal that all measurements must be made *in situ*, and best on frozen heads. According to him, the brains of females usually measure 16 centimètres in their largest antero-posterior diameter, and the largest transverse diameter is 127 millimètres. The brains of males are a little larger each way. The superior extremity of the fissure of Rolando is usually about 111 millimètres posterior to the anterior extremity of the brain, and 49 millimètres from the posterior extremity. The anterior extremity of the same fissure is about 71 millimètres from the anterior extremity of the brain, and 89 millimètres from the posterior extremity. The extremities here mentioned are the most projecting points of the hemispheres, not the ends of the lobes. He proceeds to notice certain variations which may occur in the fissures and convolutions, and also describes the appearances of the central ganglia as seen in horizontal, transverse vertical, and longitudinal vertical sections. He next describes the relations of the parts of the brain to the external surface of the skull. After referring to the labours of Gratiolet, Broca, Heffler, and Turner, he gives the result of his own observations, which were made after the method devised by Broca, by boring holes with a gimlet, and putting in splinters to mark the places.

1. The parieto-occipital fissure corresponds with the summit of the angle of the occipital bone. The extremity of the occipital lobe which rests on the tentorium corresponds with the external occipital protuberance, so that it is easy to determine the position of the cuneus.

2. Immediately in front of the lambdoidal suture the quadrilateral lobe lies in the great longitudinal fissure, and the parietal lobule in the convexity of the hemisphere.

3. The fissure of Rolando is far from being, as Gratiolet thought, subjacent to the coronal suture. Its posterior extremity is 45 millimètres behind the vertex in the female, and about 47 or 48 millimètres in males. At its anterior extremity the fissure approaches the coronal suture, but stops 1 centimètre above it. The external extremity of the suture corresponds with the interval between the two folds of the third frontal convolution. The anterior extremity of the fissure of Rolando is 25 to 30 millimètres posterior. Thus it may be deduced that the posterior parts of the frontal convolutions, the ascending frontal, and all between the fissure of Rolando and the parieto-occipital fissure lie below the parietal bone. The position of this fissure is of especial interest, as it is in the convolutions which bound it that physiological experiments and anatomico-pathological observations have localised most of the psycho-motor centres. Nearly all the region covered by the parietal bone, is supplied by the middle cerebral artery.

4. The sphenoidal excavation which lodges the anterior extremity of the temporo-sphenoidal lobe may be prolonged so as to lie between the orbit and the temporal bone, so that a wound made by a sharp instrument might injure this part of the brain before entering the orbit; and this peculiarity may exist on only one side.

Certain pathological conditions may alter the relations of the fissure of Rolando; these may be divided into two groups:—

A. Changes due to alterations in the relative sizes of different parts of the brain.

1. In some cases of congenital arrest of development of the anterior lobes, as in idiocy, the anterior extremity of the fissure may be nearer the anterior extremity of the brain.

2. In cases of atrophy from disease, as after amputation of a limb in childhood, as in a case of M. Charcot's, where the posterior extremity of the fissure was advanced 5 millimètres.

3. In cases of old destructive lesions of the convexity.

B. Changes of relation due to particular dispositions of the cranium.

1. By artificial deformities, such as that produced by a bandage which elongates the head posteriorly, the posterior extremity of the fissure may be thrown forwards 10 to 15 millimètres.

2. When the meso-frontal suture continues permeable to an advanced age, the frontal lobe may develop anteriorly instead of posteriorly; the two fissures may approach the vertex.

He passes finally to consider how these relations may be recognised on a head covered by the integuments. The external extremity of the coronal suture is situated about 1 or 2 millimètres above or below a plane passing through the superciliary ridge and 15 to 20 millimètres behind the external angular process of the frontal bone. A vertical section made here would pass through the third frontal convolution and amputate the anterior extremity of the nucleus caudatus. The anterior extremity of the fissure of Rolando is 25 to 30 millimètres posterior, and a little above this point. In order to determine the position of the posterior extremity situated 45 millimètres (in the female and a little more in the male) behind the vertex, it is only necessary to recognise the vertex. To find this, the cranium must be placed resting on the superior alveolar process and the condyles; the vertex will then be in the

line drawn perpendicular to this plane through the external auditory meatus; it is easy to put the head in this position, and otherwise the point of intersection of the sutures may often be felt. This auriculo-bregmatic plane (Busk) is about 30 millimètres behind the external extremity of the coronal suture, and in consequence in the neighbourhood of the anterior extremity of the fissure of Rolando. A vertico-transverse plane parallel to this auriculo-bregmatic plane drawn through the posterior extremity of the fissure of Rolando gives approximately the posterior limit of the optic thalamus. This last plane passes always or nearly close to the point of union between the parietal, temporal, and occipital bones, and consequently behind the mastoid process. The same plane gives the posterior limit of the island of Reil, and a little behind is the posterior extremity of the fissure of Sylvius and the angular gyrus. A horizontal plane passing about 45 millimètres below the convexity of the head will give the superior limit of the central ganglia. The position of the parieto-occipital fissure corresponding to the lambdoidal suture is usually easily made out by palpation, but otherwise corresponds to a plane passing through the minimum transverse frontal diameter. By the aid of these data it is possible in cases of wounds of the head to determine at least approximately what portion of the brain is injured, and in cases where necropsies cannot be procured, this proceeding may aid in the solution of the problems of functional localisation. In conclusion, he relates the case of a man who suffered from convulsions of the left orbicularis and zygomatici, after a wound caused by a fall on his head when drunk. The cicatrix was visible, and there remained an irregularly four-sided depression of the parietal bone, 15 millimètres square and 2 to 3 millimètres in depth. It was situated upon a horizontal line, passing from the summit of the occipital bone to the transverse minimum frontal diameter, and about 1 centimètre behind a vertical line, passing through the posterior limit of the mastoid process. On comparing the head of the patient with crania, on which were drawn the convolutions, whose relations had been determined by the preceding method, it was found that the lesion corresponded to the posterior part of the gyrus angularis. It is most interesting to notice that it is precisely in this region that Ferrier has localised the motor centres for the muscles of the eye and the eyelids.

RECENT PAPERS.

Note on the Changes in the Liver, following on the Ligature of the Ductus Choledochus. By MM. Charcot and Gombault. (*Archives de Physiologie Normale et Pathologique*, May and June, 1876.)

PATHOLOGY.

MEYER ON ANEURISMAL CHANGES OF THE INTERNAL CAROTID IN THE INSANE.—L. Meyer (*Archiv für Psychologie* Band vi. p. 84) regards disturbance of the circulation in the brain as an important factor in the production of psychical disturbances. Whilst up to this time the intracranial vascular area has been specially studied, he directed his attention to the internal carotid, proceeding from the view that long-continued and intense disturbance of its peripheral circulatory channels—

the convolutions of the cerebrum—must react on the condition of the trunk of the vessel itself. In all cases which the author investigated, he found the changes above referred to. In the thirty-one observations given, disease of a local sharply defined area of the internal carotid was observed. The disease extended from the origin of the vessel, almost always surrounding it in a circular form, extending for eight millimètres to almost one centimètre upwards, and ending there suddenly and sharply defined. Upwards these limits were never surpassed, but sometimes the lesion extended lower, passing even into the common carotid. The changes consisted in arterio-sclerosis, generally in its later degenerative stages, mostly in the form of circular calcification. Further, and chiefly at the lower margin of the altered area, there was a change in the arterial wall, which on microscopic section was seen to be due to simple thinning of the tunica media, whilst the intima remained intact. Thus partial dilatations of the vessel were formed. Frequently, however, the whole diseased part was dilated, and in eight cases distinct aneurisms were found, which considerably exceeded in size the circumference of the common carotid.

WM. STIRLING, D.Sc., M.D.

TUCK AND JACKSON ON A RARE FORM OF MONSTROSITY.—In the *Boston Medical and Surgical Journal* for April 20, Dr. Tuck, Visiting Physician of the Boston Lying-in Hospital, and Dr. J. B. S. Jackson, Professor of Pathological Anatomy in Harvard University, describe a remarkable case of monstrosity. A woman, aged thirty-two, about eight months pregnant, was delivered in the Boston Lying-in Hospital of twins; the first was dead, and was well formed; the second, which was removed with some difficulty, is the subject of the following description.

The fœtus consisted of a trunk and two lower extremities. The first terminated superiorly in a large rounded fleshy mass, as is usual in this form of monstrosity. The extremities were well developed excepting the toes, of which there were four only on each foot, and upon one of them the two smallest were fused. The whole length of the fœtus was 10½ inches. Upon the anterior face, and 4½ inches from the rounded upper extremity, was a flaccid mass about the size of a pigeon's egg, covered with integument, which must have represented the head. Upon each side of this mass, and 3¼ inches apart, was a small but well-marked dimple-like depression in the skin, which probably showed where the upper extremities would have been if they had existed. About an inch below the fleshy mass above described was the umbilical cord, and by the side of it a protrusion of three or four inches of intestine, which had been covered by a thin membrane that had burst. An inch or two below the umbilicus was a tolerably developed scrotum, but there was neither penis nor anus. The great mass of the trunk, the greatest circumference of which was fifteen inches external to the skeleton, consisted, as is usual in the acephalous fœtus, of a coarse fibro-cellular tissue, very tough and very cedematous, but there were besides in the posterior and upper portion a considerable number of cysts lined by a delicate serous-looking membrane, several of which would have held two or three ounces of fluid.

Of the internal organs, the heart, lungs, stomach, liver, spleen, and testicles were wanting, as was also

the diaphragm. In the thorax was a large quantity of coarse, white, and very tough fibro-cellular tissue, with less of the same in the abdomen. The aorta, which was of sufficient size, and in its usual relations to the spine, terminated not far below the upper extremity of this last in several small branches, and inferiorly gave off a large hypogastric artery upon the left side, but the right was wanting. There was a small intestine, $19\frac{1}{4}$ inches in length, and terminating superiorly in a *cul-de-sac*; also a large intestine, that seemed to open freely into the fundus of the urinary bladder. The cæcum was about one half of an inch in length, and sufficiently developed, but blunt, as in one of the lower animals, and entirely wanting the tapering appendage that is to form the appendix cæci. Most conspicuous in the abdomen were a large kidney and a suprarenal capsule. The first was situated mainly upon the right side, and the last wholly upon the left.

From the kidney, and at some distance apart, arose two ureters, one of which was more than two lines in diameter, and ended near the bladder in a *cul-de-sac*; the other, which was large throughout, dilated at one part and rather suddenly to the size of the end of the forefinger, and finally opened into the bladder not far from the point of entrance of the intestine. The bladder was of an oval form, about the size of a large nutmeg. Its contents, if there were any, were not ascertained, and it was an interesting negative fact that it was neither distended nor thickened, as it has been found to be in some other cases, in which there was no external outlet. When the intestine was cut across and inflated, the air passed freely into the bladder, ureters, and pelvis of the kidney. The question that arose as to this last organ, whether it was to be regarded as a single one or the fusion of two, seems to be an open one.

The skeleton consisted mainly of a spine, thorax, and lower extremities. The first was well developed so far as it extended. Of the cervical vertebrae, however, there were three or four partially fused or irregularly developed, and the lowest one only was normal. Inferiorly the spine terminated in a most remarkable manner, in the sacral region. This lower portion ended quite bluntly, and the opening of the vertebral canal was fully one-fourth of an inch in diameter. The pelvis was well developed, as were the lower extremities, but the ischia were somewhat approximated and connected by a marked fibrous band.

Of the ribs there were thirteen on each side, well developed; but upon the right side, from the second to the fifth inclusive, they were partially fused.

The sternum was formed in two lateral halves and widely separated, but connected upon each side, as is usual, with the cartilages of the ribs. Over the upper left rib was a flattened bone of a somewhat triangular form, one-fourth of an inch or more in diameter, which undoubtedly represented the scapula. Also near the upper extremity of the spinal column, and somewhat anterior to it, was a small curved bone somewhat suggesting the body of the hyoid, or perhaps the lower jaw, its length being six lines or more, and its diameter about two lines.

PROFESSOR HUXLEY.—Professor Huxley has started on a tour through the United States. It is understood that the tour is not a lecturing one, and that the Professor has only consented to deliver three or four lectures.

MEDICINE.

BACCELLI AND VALENTINER ON THE DIFFERENTIAL DIAGNOSIS BY PHYSICAL SIGNS OF DIFFERENT KINDS OF PLEURAL EFFUSION.—No. 21 of the *Berliner Klinische Wochenschrift* for 1876 (May 22) contains a brief communication from Dr. Valentiner of Ober-Salzbrunn, now at Rome, containing the results of many years' clinical studies by Professor Baccelli, in the Hospital Santo Spirito at Rome,* on the transmission of sounds through varying kinds of fluid in the pleural cavity. Hitherto we have been taught that it is possible by means of physical examination, to diagnose the presence of fluid in the pleural cavities, but that no auscultatory differences resulted from different kinds of fluid; in other words that dropsical, sero-fibrinous, and purulent fluids were all alike in the transmission of sounds to the ear of the listener.

Baccelli's work goes to prove the very opposite; namely, that the variety in the auscultatory phenomena will enable us to form an opinion as to the nature and constitution of the fluid in the pleural cavity. In order to form such a precise diagnosis, all disturbing sounds must be as far as possible excluded. The person whose chest is being auscultated should turn his face whilst speaking in a direction which is, as nearly as possible, opposite to a diagonal drawn through the very middle of the effused fluid. The ear which auscultates should be pressed close against the chest which is examined, and the free ear should be closed with the index-finger of the corresponding hand. By auscultating in this method, Baccelli has found that the thinner and more homogenous the fluid in the pleural cavity is, so much the more easily, perfectly, and to greater distances will it transmit the vibrations of the voice, and even whispers. The principal conduction of sound is at the lower part (basis) of the collected fluid; whispered words are, however, most clearly accentuated, along with bronchial expiration, when the fluid is nearly homogeneous (serous effusions). The upper part of the effusion conducts sound worst, for there neither bronchial breathing nor loud talking can always be heard. In proportion to the thickness of the fluid, the conduction of sound is hindered. Hence effusions with fibrinous flakes, or with blood and pus-corpuscles, conduct sounds badly. A true empyema is the worst conductor of sound of all the effusions. Fluids with granular corpuscles, fat, and fat-crystals, and other not morphological or fibrinous elements, behave, as regards auscultation, very much like hydropic effusions. The physical explanation appears to be as follows. Unlike gases, fluids conduct tones with intensity proportioned to their lightness and homogeneity; whilst the waves of sound are conducted somewhat more quickly, but with diminished intensity, through thicker and heterogeneous fluids, which are mingled with elastic, solid bodies. In the case of mixed coagula and corpuscular elements, as well as in the case of exudations enclosed in thick, villous membranes, there is, in consequence of this mixture and variety of conducting media, more and more reflection [?] refraction] of the sound-waves, instead of

* Sulla trasmissione dei suoni attraverso i liquidi endopleurici di differente natura. Lezione clinica di Guido Baccelli. *Archivio di medicina, chirurgia, ed igiene*, 1875, fasc. VII e VIII.

their being conducted in almost straight lines, as in the case of homogeneous endopleural fluids, which are strong conductors. At the point where the lung is most compressed, towards the base of the exudation, the sound-waves are probably reflected but little, and thus little decomposed. In other words, they are not much affected by interference at this spot. It is, perhaps, on similar acoustic principles that a pericardium so distended with fluid as to be absolutely dull on percussion, often conducts bronchial râles from adjacent portions of lung with remarkable clearness [Skona's consonance, or phenomena of resonance of Baccelli].

The importance of deciding on the nature of the contents is obvious, in relation to paracentesis thoracis.

Nine clinical cases illustrative of these views are appended to the Italian original, which the German translator omits, because, as he justly remarks, all large hospitals have ample materials of their own for proving the correctness of this theory.

HOISEL ON A SUCCESSFUL CASE OF PARACENTESIS THORACIS.—The Vienna *Medicinisch-Chirurgisches Central-Blatt* of June 2, 1876 [no. 22, XI. Jahrgang] reports the following case at some length. The wife of a landed proprietor of Opoka, in Styria, aged thirty-nine, was attacked with left-sided pleurisy in the ninth month of pregnancy. Four days afterwards she was, a little prematurely, confined of a healthy child; but, in spite of these unfavourable circumstances, the puerperal condition was not much affected. Her dyspnoea, however, increased, in spite of remedies, and four weeks after the beginning of her illness, the heart was pushed far over to the right, and the physical signs showed that the left pleura was nearly full of fluid. Her dyspnoea was extreme. After five or six days' trial of another diuretic (the iodide of potassium) it was resolved to tap the chest. This was done in the fifth intercostal space, in a line with the left axilla. An elastic tube was attached to the trocar, and the end placed in a glass of water, standing in a larger vessel. After three quarters of an hour three litres (= $5\frac{1}{4}$ pints) of greenish-yellow sticky fluid, which coagulated on exposure to air, were withdrawn. A considerable quantity was, however, left behind, for fear of syncope. In three days all this had disappeared, if physical signs be reliable. In a few days more she was out of bed and doing domestic duties. Six weeks afterwards, her health was pronounced excellent.

W. BATHURST WOODMAN.

BOWDITCH ON EMPYEMA AND THORACENTESIS. In the *Cincinnati Lancet and Observer* for June, Dr. Bowditch, of Boston, states that he has up to this time performed thoracentesis 328 times, on 207 patients, and that none of his patients have died immediately, or in consequence of the operation. He explains the large number of deaths after the operation, in Europe, by the desire of the operators to do too much, and thus prolong the operation beyond the time proper for the patient. They desire to get out all the fluid that can be drawn. His own rule is to stop suction the moment the patient begins to suffer from any uncomfortable symptoms—stricture of the chest, severe harassing cough, etc. A mild cough is a favourable sign, as it indicates expansion of the lungs. This rule applies to all cases, whether serum, pus, bloody or foetid fluid be found

in the pleural cavity. Dr. Bowditch asserts that nearly all children with empyema recover after thoracentesis. Adults with recent trouble are in a more favourable condition for recovery than when the disease is chronic. Sometimes after repeated operations phthisis is liable to set in. In such a case the repeating of the aspiration is a bad mode of proceeding. It is better, if after aspirating once, or at most twice, a constant tendency to the re-accumulation of pus is found, to make a free and permanent opening. This may be made by means of a trocar and cannula just large enough to admit the passage of a drainage-tube. Shorter cannulas must be substituted for the one originally used, according as the cavity diminishes in size. A free incision is more painful, but is the better operation of the two. With regard to the subsequent treatment, as long as laudable pus is being thrown out, and the lung is expanding, and the patient is improving, Dr. Bowditch does nothing. He thinks that patients are often made worse by too much 'washing out the cavity.' If, however, the patient fails, has hectic, etc., he uses injections of warm water, which often produce the happiest results. He has not used carbolic acid, but thinks that it may be useful. Constant drainage is his rule. Where the fluid drawn is serous he prefers repeated aspiration to a permanent opening. If the serum be bloody at the first operation he never makes a permanent opening, for the case is then one of malignant disease. Empyema may occur in persons previously healthy; but a bad constitution is often at the bottom of the matter. As sequelæ, Dr. Bowditch has never met with Bright's disease or enlarged liver, but has met with tuberculosis and enlargement of the heart in a few cases. In these last cases, though the fluid did not reaccumulate, the lung never regained its free expansion, and after months of trouble the patients died suddenly with cardiac symptoms.

PEITAVY ON RESECTION OF THE RIB IN EMPYEMA.—In the *Berliner Klin. Woch.* May 8, 1876, Dr. Peitavy records two cases of empyema, treated by resection of a portion of the rib, for the purpose of permanently widening the aperture, and so facilitating both the discharge of pus, and the injection of fluids. In the first case, aged sixty-four, pus was removed by incision six weeks after the first symptoms. In spite of washing out the chest by the double catheter, injection of tincture of iodine, and the use of a drainage-tube, pus was retained and the patient suffered from fever with evening exacerbations, rigors, loss of appetite, and increasing weakness. Attempts to dilate the aperture with laminaria caused great pain, and it became impossible to wash out the chest properly. Finally, five months after the incision, a portion of the seventh rib, somewhat more than an inch in length, was removed with the chain-saw. Pus escaped, a drainage-tube was inserted, and the symptoms were relieved from that time. The tube was removed after a month, and in another fortnight the wound had closed. In the second case, aged fifty-six, the result was less striking. Two weeks after the first incision, and only seven weeks after the first symptoms, a portion of the eighth rib was excised and a tube inserted. Fever however continued, and as injections caused coughing and dyspnoea, the tube was removed after twelve days. The case was complicated by a bronchial fistula, but was completely cured about two months after the resection. A third case of empyema is recorded from the

practice of Professor Simon, in which resection of the rib acted not so much by allowing the free discharge of pus, as by permitting the approximation of the ribs and the obliteration of the cavity. Peitavy prefers resection to Fräntzel's practice of fixing in a silver cannula, because it is less painful, less irritating to the pleura, and tends to diminish the size of the cavity.

F. TAYLOR, M.D.

STITZER AND ROCHS ON A RARE CASE OF CHRONIC GENERAL PERITONITIS, WITH PROTRUSION OF THE NAVEL.—Staff-Surgeon Stitzer, M.D., and Assistant-Surgeon Dr. Rochs, of Mainz, report the following case in the *Berliner Klinische Wochenschrift* of May 22 and 29 last [nos. 21 and 22 for 1876].

The patient, Louisa K——, daughter of a refreshment-room proprietor, was the child of healthy parents, whose family history was extremely good, and herself enjoyed good health, until her eighth year. None of the family were scrofulous. Louisa was a very lively child. In her eighth year (1868) she had measles. It was not, however, until some months afterwards that her parents remarked that her abdomen began to enlarge. Her general health was still little affected. In the spring of 1871, however, the increase of the fluid, the dyspnœa, etc., induced them to consent to her being tapped. Ten *schoppen* [a little over a gallon] of yellowish-green and sticky fluid were removed. There was no particular œdema of the lower extremities. A few days afterwards she was quite lively. For nearly a whole year she continued apparently quite well. A photograph of the child at twelve represents her as blooming and well-formed. But towards the end of the year the abdomen began again to enlarge a little, and in the spring of 1872 she was as large again as ever. She was tapped again, and this time one and a half gallons (fifteen *schoppen*) were removed. Though not quite so well as after the first tapping, she never kept her bed, except for a day or two. Appetite was good, and she was lively, though she had lost her fresh colour. Again the belly enlarged, and a third tapping in 1873, in the summer time, removed thirty *schoppen* (more than three gallons) of fluid like that of the former ones. About four months after this the navel began to protrude, at first like a small bean, but after about fourteen days, it was an elastic fluctuating swelling, about the size of a hen's egg. It remained so for some time, and then, as the abdomen enlarged, it protruded still more. In the spring of 1874, the fourth operation for the removal of the fluid consisted in opening the swelling at the navel with a lancet. More than four gallons of fluid escaped this time. The navel collapsed completely, but the child was faint and weak, and confined to bed for a considerable time. The treatment was, perhaps, not the best possible. After this she was never so well again as after the former tapplings, being weak and soon tired. Steel drops did not do much good. The lower extremities now began to swell, she began to lose flesh, the skin became slightly jaundiced, her appetite failed, and digestion was impaired. A new feature appeared in the shape of pains about the navel, stomach, and liver—most severe about the navel. The abdomen again enlarged, and the navel again protruded. She was now about fifteen years of age. About this time (November 18, 1875) Drs. Stitzer and Rochs first saw her. She was then unable to lie down or move about. She sat on a sort of chair with arm-rests,

the lower extremities widely abducted and almost deprived of motion, resting on two foot-stools. She was much emaciated. The face had a gray icteric tint; the lips, etc., were cyanotic. There was much dyspnœa and great pain, increased by pressure, in the region of the navel. The circumference of the belly at this point was rather more than six and-a-half feet. The swelling of the navel itself was about sixteen inches long, and resembled a long sausage, with an average circumference of about ten inches. The superficial veins were much distended. The umbilical swelling showed a very dark colour of the skin, in the centre almost like a negro's. There was uniform dulness on percussion all over the front of the abdomen, and over the umbilical tumour. The heart-sounds were clear, and free from bruit. There was no albumen in the urine, which contained a good deal of bile-pigment, and lithates. There were no external signs of puberty. The skin was harsh and dry. There was no enlargement of glands. Under these circumstances, any diagnosis of the cause of the ascites was difficult. It was suggested that the exanthem might have been scarlatina, and not measles. A careful inquiry, however, appeared to negative this. The prognosis was of course unfavourable. Just as it was proposed to tap once more, intercurrent right-sided pneumonia set in. When this subsided, an exploratory puncture was made through the tumours at the navel, and about one and three quarter pints of fluid containing sodium chloride, bile-colouring, and albumen, but no succinic acid, no hooklets or scolices, but a number of small, strongly refractive, yellow-tinged, irregularly shaped corpuscles, was thus removed. The opening then became plugged with a coagulum. Opiates were ordered, as she could not sleep. As some slight relief had been given by the puncture, nothing more was done. The jaundice deepened, the weakness increased, and she died on December 4, 1875, apparently from exhaustion, there being no œdema of the lungs. The *post mortem* examination was made the next day. Permission was obtained only to open the abdominal cavity. *Post mortem* rigidity was absent. On opening the abdomen, very little fluid escaped, of a yellowish tinge. The whole abdominal cavity, from the diaphragm which extended as high as the fourth ribs to the true pelvis, was covered with an albuminous gelatinous mass, adhering together, of a yellow tint, though streaked with blood in places. It was easily separated from the underlying bowels, liver, pancreas, and spleen, but with more difficulty from the posterior walls of the abdomen. The whole of the intestines, including the stomach, were formed by adhesive peritonitis into a great ball ('zu einen grossen Knäuel'). The great omentum appeared wanting, being converted into the jelly-like mass previously noted. The sigmoid flexure and peritoneum near it, and the mesentery, were very striking in appearance, like red cylindrical bodies, owing to the vascular injection. The parietal peritoneum was enormously thickened. Cord-like adhesions of some thickness were met with in numerous parts, between the parietal and intestinal peritoneum. The liver, atrophic and nutmeg-like, was so universally adherent that it had to be cut out. The gall-bladder contained no gall-stones, only a little thick but still fluid bile. The bile-ducts were all pervious. There was no degeneration or disease of the mesenteric or other glands. The spleen was normal, except for a little enlargement and thickening. The pancreas, kidneys, bladder, ureters, and genital organs were

all normal. The distended navel contained a similar gelatinous mass to that in the general cavity, with which it freely communicated. The abdominal veins were somewhat dilated, otherwise normal. The same may be said of the arteries. The muscles, and subcutaneous tissues of the abdominal wall were œdematous, the œdema being of a semi-solid, glutinous kind. The result of microscopic examination of the gelatinous mass was as follows. The jelly itself, a soft, tremulous tissue, was amorphous; it contained, 1. A rather small number of grey, globular, nucleated cells, filled with granular contents, which were, on an average, three or four times as large as blood-corpuscles; 2. Smaller cells, apparently blood-corpuscles, or like them; 3. A number of very small, strongly light-refracting, yellowish, and very irregularly shaped granules, apparently the *débris* of cells. The jelly-like mass was traversed by numerous and sometimes very closely arranged connective tissue fibres. There was no other trace of organisation.

Epicrisis.—The *post mortem* examination disclosed a general chronic peritonitis, with gelatinous transformation of the previous exudation. It also showed; 1. Extraordinary thickening of the parietal peritoneum, with formation of new blood vessels; 2. Similar thickening of the visceral layer; 3. Similar transformation of the parietal layer of the navel; 4. Moderate formation of free membranes on the liver and diaphragm; 5. Cord-like adhesions between the visceral and parietal layers; 6. Matting together of almost all the abdominal organs; 7. Copious peritoneal effusion in the abdominal cavity; 8. The same in the distended navel; 9. Conversion of the great omentum into a gelatinous mass.

The dark pigmentation of the skin in this case was not due to poulticing, since no poultices were used. [See Bamberger, *Krankheiten des Chylo-poëtischen Systems*, pp. 692, 693.]

This case is analogous to the one briefly described by Förster (*Specielle Pathologische Anatomie*, p. 96.)

W. BATHURST WOODMAN.

GANGOLPHE ON MITRAL BRUIT IN JAUNDICE.—Dr. Gangolphe (*Du Bruit de Souffle mitral dans l'ictère*, Thèse de Paris, 1875) has seen nine cases in which a mitral regurgitant murmur accompanied jaundice. It was most marked in those cases in which the pulse was slow, and usually disappeared when the slow pulse disappeared. Gangolphe thinks the murmur due partly to a dilatation of the heart, but chiefly to a paralysis of the papillary muscles, caused by the circulation of the biliary principles in the blood. He refuses to allow anæmia any share in the begetting of the murmur, although in some cases, it will be noted, the murmur was prolonged into the arteries. The paralysis of the papillary muscles is caused by a fatty degeneration of the heart structure, secondary to the action of the biliary poisons.

This thesis is an interesting and valuable contribution to the literature of jaundice.

J. WICKHAM LEGG, M.D.

LEGG ON THE SLOW PULSE IN JAUNDICE.—Dr. Wickham Legg has laid before the Royal Society (*Proceedings*, April 1876) the result of his work on the slow pulse in jaundice. This he finds to be doubtless due to the action of the biliary acids; probably upon some part of the heart itself, since the frog's heart, when separated from the body, and fed with an artificial circulation, shows the slow pulse

when acted on by the bile-acids. Of the three factors in the heart's movement, the vagus, the muscular walls, and the ganglia, the vagus is first excluded, since the slow pulse still appears when the inhibitory function of the vagus is destroyed by atropine. Then, contrary to the opinion of Traube and Johannes Ranke, the bile-acids are found to have no influence upon striped muscular tissue, whether administered in large or in small doses by hypodermic injection. Further, the bile-acids were found to have no special action upon the movements of the ventricle of the heart, when this last was separated from the auricles. There remains, therefore, only the third factor, the ganglia, and it is to the action of the bile-acids upon these that the slow pulse in jaundice is attributed.

It is found, likewise, that the bile-acids have no effect on the rate of movement of the lymphatic hearts. The reflex irritability is greatly diminished by them.

GOLDSTEIN ON SYPHILITIC DISEASE OF THE LIVER.—The following case is reported by Dr. L. Goldstein in the *Berliner Klinische Wochenschrift*, May 8, 1876. The patient, forty-three years old, had been infected with syphilis about twenty years previously, and four years ago had had rheumatic pains in the shoulders, and pain in the right side. Recently he had had icterus and swelling of the feet. He was anæmic, and thin, with dirty yellowish tinge of the skin; but there was no glandular swelling, no syphilitic eruption, and no prominence or tumour of the liver; indeed, this organ was apparently smaller than normal. After a time hæmatemesis occurred, and the stools contained blood. The spleen was not enlarged. Ascites developed, and after a violent attack of hæmatemesis he died, eighteen days from the first loss of blood. In the right lobe of the liver was a wedge-shaped mass of connective tissue, measuring 3 inches long by 2 inches broad, and from 1 to 2 inches thick; scattered through this were numerous cheesy nodules of various sizes, bounded by dense fibrous bands. From the wedge-shaped mass stout bands of fibrous tissue stretched downwards between the larger branches of the portal vessels. The whole surface of the liver was deeply marked and deformed by cicatricial contractions, and the cut surface was finely nodular, with a finer or coarser network of irregular fibrous bands. Microscopically these bands were rich in nuclei, though many presented fatty degeneration of the new tissue. The cheesy nodules consisted of a finely granular detritus. The liver itself was small, with an adherent capsule; it was not lardaceous. The spleen and kidneys were congested, but otherwise normal.

F. TAYLOR, M.D.

DE BONIS ON EPILEPTIC PHENOMENA IN A CASE OF CEREBRAL TUMOUR.—In an article in the *Annali Clinici dello Spedale Incurabili di Napoli*, anno i. fasc. 2, Dr. T. De Bonis reviews the recent doctrines regarding epilepsy, and accepts vascular spasm as an explanation; in short, he recognises epilepsy as a vaso-motor necrosis of the brain. He relates the case of a man, aged sixty, who first suffered severe pains in the frontal and parietal regions, extending to the occiput; the pain was intermittent. Convulsions afterwards appeared; they were preceded by noises in the ears and vertigo, and were repeated several times in the day. When young, he had had gonorrhœa, soft ulcers, and syphilides. From the anamnesis and the symptoms

observed during the attack, the diagnosis was made of epilepsy with chronic meningitis from cerebral syphilis, probably with gummata disseminated in the anterior and middle lobes of the right hemisphere, and encephalitis affecting the origin of the seventh pair. Most of the symptoms—paleness, dilatation of the pupil, clonic convulsions, etc.—were principally manifested on the right side. At the necropsy, there were found congestion of the membranes of the brain, chronic meningitis, and seven gummatous masses in the cortical substance towards the upper part and the base of the cerebral lobes, some being of old, others of recent formation. There was no appreciable lesion of the medulla oblongata, pons Varolii, cerebral peduncles, hippocampus, etc.

Dr. De Bonis remarks that this case shows that from the cerebral mass there may arise irritations, which are directed along the converging fibres to the medulla oblongata and peduncles, determining a super-excitation of the vaso-motor centres, whence arises spastic contraction of the vessels, as shown by the pallidity of face and loss of consciousness. He thus explains the convulsions by spastic ischæmia of the nervous centres.

A. HENRY, M.D.

FLECKLES ON THE OCCURRENCE OF ALBUMINOUS URINE IN DIFFERENT CHRONIC AFFECTIONS, AND ON THE UNSUCCESSFUL RESULT OF CARLSBAD THERMAL TREATMENT IN CHRONIC DIFFUSE INFLAMMATION OF THE KIDNEYS.—Dr. Fleckles (*Deutsche Medicinische Wochenschrift*, May 13, 1876) has observed albuminuria in Carlsbad, as a symptom of various pathological processes and not as an indication of diffuse inflammation of the kidney or of Bright's disease, in catarrh of the urinary organs, in lithiasis, in atrophy of the liver, in spleen and in intermittents, as also in organic diseases of the heart and of the female sexual organs. He writes as follows.

Graves and Gubler were the first who drew attention to the connection between liver disease and albuminuria. Robin and Valentin considered albuminuria to be a blood-anomaly, in which there was supposed to be present in the blood an excess of albuminoid matter, which was regarded as the cause of the albuminuria. This is supported by what is seen in Carlsbad, where albuminuria may be observed in disturbance of the digestive organs, in chronic stomach and intestinal catarrh, and in liver and spleen affections, the result of malarious disease. In that place especially, we observe that chronic blood-diseases act on the kidneys so as to make them excrete considerable quantities of albumen. These anomalies of the constitution of the blood may also often be the cause of important disease of the kidneys, especially when albumen has long been present in the blood in quantity which it cannot assimilate. Apparently there is very much the same pathologico-chemical process as in mellituria, in which it is only when there is a great accumulation of sugar in the blood that the symptoms of diabetes appear; whereas, when but small quantities of sugar are found in the blood, none of the characteristic symptoms of that disease are apparent.

Without being humoral pathologists, we can not but admit that Jaccoud has some grounds for the following generalisation. 'The alteration of the kidneys in albuminuria is only of secondary origin. It is evident that the cause of albuminuria must be found in the whole state of the constitution, as albumen is

excreted not solely through the kidneys, but through the wide extent of the healthy mucous membranes; therefore albuminuria is not always to be regarded as a sign of this or that disease of the kidneys, but as an expression of certain general disturbances of the whole organism.'

When microscopic examination of the blood reveals no casts and no blood in the urine, and when the usual signs of Bright's disease are absent, and yet albumen is present in the urine, we are warranted in assuming that we have a chronic symptomatic albuminuria, which may be the accompaniment of many altered conditions of the blood. Obstructions of the vena portæ or of the abdominal viscera often produce hyperæmia of the kidneys, and if they last long, cause albuminuria; but albuminuria is much oftener produced, as we have occasion to observe every season, by affections of the urinary organs, as in renal lithiasis, in which the constant irritation caused by the presence of a foreign body favours the production of the pathological change. We have also frequently observed it in men with stricture of the urethra, and in women with ovarian tumours and with metritis.

This accidental albuminuria does not give a very favourable prognosis, if the ailment on which it depends is of long standing, as in chronic hypertrophy of the uterus, or hereditary disposition to disease of the generative organs. On the other hand, if the affection of the generative system be of shorter standing, the prognosis is more favourable; and still more favourable is the prognosis, when albuminuria is associated with such affections as chronic stomach catarrh, chronic vomiting, or simple gastric ulcer.

The digestive organs are in these affections unable to assimilate the albuminates; but if no more important lesion, such as scirrhus, be present, a Carlsbad course followed up by one of Franzensbad, is in most cases very successful, especially if the diet be properly regulated, if aliment rich in protein be selected, and thus a limit be put on the excretion of albumen. When alterations of the blood-pressure and obstructions to the abdominal circulation or in the central organ of the circulation cause a similar condition of the kidneys and thus lead to albuminuria, the Carlsbad waters used in baths and for drinking do excellent service.

Albuminuria is also often observed in organic disease of the heart complicated with fatty liver; here too the careful and moderate use of the less warm Carlsbad springs followed by that of the iron waters of Franzensbad is often of distinct advantage. The heart-affection, it is true, remains stationary, but its more grave symptoms are mitigated, its progress is for a time arrested, the fatty liver is reduced, and the albuminuria is diminished.

In the cases of heart-disease with albuminuria that we have treated, we have (probably accidentally) observed no dropsy, or at most slight cedema of the feet; where there has been dropsy, there has been also diffuse nephritis, as proved by the microscopic and chemical examinations of the urine, and sometimes by *post mortem* sections. In organic heart-affections of long standing, caused by venous congestion by hypertrophy of the liver, or by lesions of the spleen, the careful use for short periods of the less warm sources of Carlsbad may give some relief to the symptoms, and help at least to prolong life.

Bright's disease complicated with organic heart affection, especially with hypertrophy and dila-

tation which manifests itself mostly in the left ventricle, or with fatty infiltration, is on the whole a *noli me tangere* for the use of Carlsbad waters. We have had opportunity of proving the value of a diagnostic sign of Bright's disease first pointed out by Lebert, a certain amount of infiltration of the cellular tissue over the shins, whilst the rest of the limb is nearly free from œdema. It is worth looking for. Albuminuria in diabetes always indicates an advanced stage of that disease, and such cases are not fitted for treatment at Carlsbad.

On the whole, a good deal is to be gained by Carlsbad treatment of albuminuria when it is symptomatic of liver, kidney, heart or uterine affections, of intermittents or gout, and albuminuria may be arrested, provided diffuse inflammation of the kidneys or Bright's disease is absent.

The most that can be done for Bright's disease at Carlsbad is, if possible, to improve the blood-crisis, and thus limit the loss of albumen and the pathological change of kidney associated with it.

If chronic diffuse inflammation of the kidneys, in any of the four stages of it that have been described, be sent to Carlsbad, nothing more can be done than to endeavour to regulate the disturbance of nutrition. Such cases are better suited for the saline iron springs of Franzensbad. If there be a high degree of anæmia and the nervous system be much depressed, the powerful iron springs of Pyrmont or of Spa deserve a preference; and in some few cases it is possible by the judicious use of their waters to set bounds to the elimination of albumen; whether at the same time any bounds are set to the pathological change in the kidneys we do not venture to say. In advanced cases of Bright's disease all such treatment is, of course, hopeless. But we hope that we have said enough to show that the Carlsbad waters are of use in forms of albuminuria not depending on that disease.

SURGERY.

ASHHURST ON EXCISION OF THE KNEE AND AMPUTATION OF THE THIGH FOR DISEASE OF THE KNEE-JOINT.—At a recent meeting of the Philadelphia College of Physicians, Dr. J. Ashhurst read a paper on the above subject (*New York Medical Record*, July 8). The paper began with the histories of ten cases of excision, and five of amputation, all performed by Dr. Ashhurst himself. Excision was performed three times for arthritis with

partial ankylosis, twice for arthritis with abscess, once for arthritis following small-pox, and four times for gelatinous arthritis. Nine of these cases had recovered with useful limbs, one, however, still wearing a splint, as the operation was but recently performed; and the tenth case was convalescent, and promised to have as favourable a result as the other nine. Amputation of the thigh was performed in five cases that did not admit of excision on account of the extent of the disease, or of visceral complications. One of these cases only proved fatal. This patient was fifty-one years of age, and a man of intemperate habits; and the operation was performed for acute destructive inflammation of the knee-joint following an injury to the leg. In all the other fourteen cases the arthritis was chronic, and the patients were between five and eighteen years of age.

After concluding the account of this remarkable series of cases, Dr. Ashhurst put his remarks in the form of answers to the following questions.

I. When should the surgeon abandon expectant measures in the treatment of knee-joint disease, and what may be considered the indications for a resort to operation?

II. Operative interference having been resolved upon, how shall the surgeon decide between excision and amputation?

III. When an attempt is made to save the limb by excision, how shall the operation be performed, and what shall be the after-treatment?

I. In answer to the first question it must be premised that most cases of inflammation, even of the larger joints, dependent on blows, sprains, or internal causes, are amenable in the early stages to treatment by rest and extension. Unfortunately, however, the case often appears at first so trivial, that it is neglected until it is too late for the above treatment to be efficacious. Of the ten cases of excision reported above, in only one had the disease lasted less than one year, the duration ranging in the other cases from one to six years. Dr. Ashhurst does not deny that some of these cases might ultimately have got well without an operation, but the limbs secured by the operation were immeasurably better and more useful than the withered and deformed limbs resulting from the so-called spontaneous cures. In deciding on the propriety of an operation in any particular case, the age and general condition of the patient, and the duration and stage of the affection, must be considered. Excision of the knee is not very successful in children under five years of age; these suffer more from the confinement than older children, and, Dr. Ashhurst thinks, are also more liable to the insidious development of tuberculous and other constitutional diseases. In persons past the prime of life, excision of the knee is so fatal, that it should be entirely discarded, and amputation resorted to where an operation is absolutely indicated. The most favourable age for excision is from five years to puberty.

The presence of visceral disease, as a rule, positively contra-indicates excision. An operation is seldom required in recent cases, in which rest, extension, and proper constitutional and local treatment will usually effect a cure. Dr. Ashhurst maintains that these chronic joint-affections, though unquestionably local diseases, are not of exclusively local origin, and that they require constitutional as well as local treatment. Finally, no operation should be performed as long as the disease is confined to the synovial membrane, or, even when all

the tissues of the joint are involved, as long as the integrity of the part is maintained and a hope of preserving a useful joint remains. 'But when the relaxed condition of the joint and the occurrence of consecutive dislocation show that the crucial ligaments and semilunar cartilages have disappeared; when the limb is contracted and helpless, and the patient gives a history of repeated relapses from comparatively slight injuries, or, on the other hand, when the doughy semi-elastic character of the swelling shows the existence of gelatinous arthritis (the typical "white swelling" of the older writers), an operation may be properly resorted to, even if the limb be at the time in a quiet condition. When in addition the joint is in a state of suppuration, and still more if there be caries of the articular surfaces, an operation may be considered (other things being favourable) as almost imperative.' The operation may be performed comparatively early in cases of gelatinous arthritis, in which there is hardly any tendency to spontaneous recovery.

II. Amputation should be performed in preference to excision when the patient is too young or too old, when there are visceral complications, when the disease is too extensive to allow its entire removal without taking away so much bone as would materially impair the usefulness of the limb, and when the question of the time required for recovery is important.

III. In performing the operation of excision, Dr. Ashhurst prefers the transverse incision across the front of the joint, just below the patella. He dissects back the skin and superficial fascia to the level at which he means to use the saw, then cuts directly down to the bone, and removes condyles, patella, and the diseased tissues together. The bones are divided from below upward by means of a Butcher's saw with blade reversed. The femur, in order to retain the natural inclination of the limb, should be sawn in a plane which, as regards the axis of the femur, is oblique from behind forwards, and from within outwards. The tibia should be sawn in a plane transverse to its long axis, with a slight antero-posterior obliquity. The epiphyseal junctions should not be interfered with in children; it is sufficient to remove a slice half an inch to an inch thick from the condyles, and less from the tibia. Any shreds of disorganised tissue may be cut away, but the floor of the wound must be left intact. The patella should always be removed. Tenotomy of the hamstring muscles may be necessary before the limb can be brought into position. Before the patient emerges from the anæsthesia, a posterior splint, bracketed opposite the knee, to allow daily dressing of the wound, should be applied, and left undisturbed for at least a fortnight, and better still for six weeks, at the end of which time the process of bony union will be well advanced. A straight position is the best for the limb, on account of the shortening produced by the operation.

BENNETT ON FRACTURE OF THE COSTAL CARTILAGES.—In an article on fractures of the costal cartilages, in the *Dublin Journal of Medical Science* for March, Dr. E. H. Bennett says that the circumstances under which these fractures take place are, he thinks, capable of being divided into three classes; the first including cases in which the injuries to the cartilages are of secondary importance, complications or results of more extensive and graver injuries; the second, cases where the fractures occur

from direct violence, limited in its action to the seat of fracture, and not involving the thoracic viscera gravely or the adjoining bones; the third class, certainly the least familiar, includes cases where the fracture results from the violence of coughing, or similar muscular exertion, favoured by structural disease of the lungs, pregnancy, etc. The existence of recorded cases of the accident produced in this way is sufficient to put aside the dogmatic assertion—'the accident is invariably produced by external violence.'

In the first class we have opportunities of studying the recent fractures of the cartilages, for such cases are often fatal shortly after the receipt of the injury; in the second occur the instances of united fracture, which possess a greater pathological interest than those contained in the first group. Of the existence of the third, the cases recorded by Gurlt are sufficient evidence. The majority of authors agree as to the direction of the line of fracture, yet, even here, we find some directly opposed opinions. The fracture is commonly described, in the words of Boyer, as being '*nette et perpendiculaire*,' not, as in the ribs, '*inégaie et oblique*.' Anger asserts that but a single instance of oblique fracture exists, an instance recorded in the thesis of Dr. Manuel (Paris, 1855); while, on other hand, a single authority, Gross, holds that 'the direction of the fracture is commonly somewhat oblique.'

In reference to the seat of fracture, the guarded statement of Boyer, 'that hitherto fractures of the cartilages have been observed between the fifth and eighth ribs,' deserves to be noted, for it is one which might well have been followed by more recent writers. We find in the 'Cyclopædia of Practical Surgery' the following:—'Those only which join on to the sternum seem ever susceptible of this injury,' yet many instances of fracture of the eighth and ninth ribs are on record.

Dr. Bennett relates six cases, the characters of which were:—1. Fracture of the cartilage of the first rib on one side; fracture simulating separation of the cartilage of the first rib from its rib on the opposite; 2. Oblique fracture of the third costal cartilage; 3. Fractures of the eighth and ninth costal cartilages, united with overlapping of the fragments; 4. United fractures of the sixth and seventh costal cartilages of the right side; 5. Fracture of the ninth costal cartilage, united by ensheathing callus; 6. Fracture of the eighth costal cartilage, united with angular deformity.

After commenting on the mode of union in cartilage, and on the microscopic appearances, Dr. Bennett sums up in the following conclusions.

1. Fractures of the costal cartilages may be arranged in three groups; the first containing recent fractures, which are consequences of grave injuries of the chest, and mere results of fractures of the sternum or ribs; the second, united fractures caused by limited direct violence; the third, fractures the result of muscular action.

2. The degeneration of the cartilages which precedes their ossification—the cleavage of the hyaline substance—may be regarded not only as a cause predisposing to fracture, but also as a cause determining its direction, which, in the great majority of cases, is transverse.

3. Oblique fractures are possible, chiefly as secondary injuries.

4. The callus in these fractures is developed as in

bone, the broken cartilage participating in its development.

5. The difference between the modes of union in bone and cartilage fractures consists, in the case of overlapping fractures, in the more limited development of callus in the cartilage fractures, and, in all forms of fracture, in the slowness with which the process of union would appear to be completed.

HAMILTON ON FOREIGN BODIES IN THE AIR-PASSAGES.—Professor Hamilton, of the Columbus Medical College, contributes a paper to the first number of the *Ohio Medical Recorder*, for June, in which he puts on record twenty-one cases of foreign bodies in the air-passages. He divides his cases into three groups. The first group comprises four cases. In one, part of a grain of wheat was drawn into the air-passages; in one a piece of privet leaf, and in two, bits of peanut shells; and in all four cases the foreign body was removed in a coughing fit. These cases emphasise the following point, viz. when the foreign body is known to be quite small or soft, flat and irregular, so that it is susceptible of being further softened, and enveloped by the viscid secretion of the air-passages, it is so slightly irritating, and so well adapted for spontaneous expulsion, that an operation is inadmissible.

The second group comprises two cases, in which the body was irregular, and its movements and relations could not be well estimated. In one case, the patient, a child, died suddenly, with croupal symptoms, and a piece of hickory nut-shell was found in the larynx at the *post mortem* examination. In the other, a pregnant woman inhaled a shirt-button with a pin stuck in it. No marked symptoms were excited, and, after a few weeks, the button was coughed up, followed, in a few months, by the pin.

The third group includes fifteen cases. In all of them the foreign body was hard, smooth, and round in outline; in one it was a grain of pop-corn in its natural state; in one a locust-seed; in three a large full bean; in three a water-melon seed; in six a grain of common field-corn, all dry and hard, except one, which was a grain of roasted green corn. In three of these cases no operation was performed; one of the patients died of broncho-pneumonia in seven days, and the other two coughed up the foreign bodies after several weeks, and recovered. In the remaining twelve patients there were thirteen operations, the foreign body being found in most cases at rest in the right bronchus, never fairly in the left. In six cases the body was expelled at once, and in the rest within from one to seventy-two hours. Where the body remains without motion in the bronchus after the operation, Professor Hamilton advises that the patient be kept within reach, for sooner or later some movement will put it in motion, and then, on simply dilating the opening, expulsion will take place. One case died of broncho-pneumonia, which had existed before the operation. In three cases laryngo-tracheotomy was performed, followed by impairment of voice in two, and the same result followed one of the tracheotomies. The patients were all under seven years of age, and the foreign bodies had been in the air-passages from two hours to ninety-six days.

On adding these fifteen cases to a number of cases tabulated by Dr. Weist, of Richmond, in which the foreign bodies were similar to those in our third group, we find that out of forty-five cases treated without operation, fourteen, or thirty-one per cent.,

died, while out of forty-six treated by operation, twelve, or twenty-six per cent., died; a difference of five per cent. in favour of the operation. These figures prove the incorrectness of the opinions widely spread among medical men, that foreign bodies in the air-passages absolutely demand operation, and that the cases are of such emergency as to preclude sending a long distance for competent surgical aid.

Professor Hamilton, for obvious reasons, opens the trachea above the isthmus of the thyroid gland, and divides usually four of the tracheal rings. Where this cannot be done without injuring the isthmus, he divides the cricoid cartilage and part of the crico-thyroid membrane, which, however, is almost necessarily followed by impairment of voice.

FRUSCI ON A CASE OF ANGIOMA PRESENTING PERIODICAL TURGIDITY.—In the *Annali Clinici dello Spedale Incurabili de Napoli*, anno i. fasc. 2, Dr. Frusci describes the case of a laundress, aged eighteen, who for four years had been subject to a blue coloured tumefaction, accompanied with intense pain, on the right fore-arm and hand. This swelling appeared in March of each year, and lasted twenty or thirty days. Dr. Frusci diagnosed it as a deeply seated diffuse venous angioma. He cannot explain the annual recurrence on the hypothesis of vasomotor action; he remarks, however, that Bell, Launay, Esmarch, Kreysig, Porta, and Virchow have observed periodicity in the development and exacerbation of sanguineous tumours.

A. HENRY, M.D.

VIENNOIS ON THE CAUSES OF REAL SHORTENING OF THE LIMB AFTER COXALGIA WITHOUT DISLOCATION OR DISPLACEMENT OF THE HEAD OF THE FEMUR.—M. Viennois (*Gazette Hebdomadaire*, January 7, and *Journal des Connaissances Médicales*, February 15) divides coxalgia into five varieties: 1. Coxo-femoral arthritis or true coxalgia; 2. Primary osteitis of the upper end of the diaphysis of the femur; 3. Primary osteitis of one of the bones forming the cotyloid cavity; 4. Inflammation of bones close to the joint, but not in connection with the synovial membrane (for instance, the great trochanter); 5. Periosteal inflammation developed in the connective tissue and tendons of the pelvi-trochanteric region. The fourth and fifth varieties are pseudo-coxalgic affections.

In the first variety, or true arthritis, the synovitis is not a cause of much shortening. It is only when the epiphyseal end of the femur is attacked primarily or simultaneously, that the longitudinal growth of the limb is considerably disturbed. The cause of the shortening is to be sought in the general atrophy of all the tissues of the limb induced by long rest, immobilisation, and disuse.

In coxalgia from primary osteitis, on the other hand, the growth of the bone is directly concerned, and shortening is the speedy result; the younger the subject, the more obvious is this.

Shortening from the first cause is to be combated by electricity, friction, and gentle traction by elastic bands; and, moreover, by keeping the limb in a state of abduction, giving it an apparent lengthening, we may diminish the inevitable effects on its functions. The author follows views expressed by M. Ollier.

OTIS ON GLEET AND ITS RELATION TO URETHRAL STRICTURE.—Dr. F. N. Otis states (*American*

Clinical Lectures, vol. i. p. 10) that in cases of urethritis (not venereal in origin) or gonorrhœa (of venereal origin) where complete recovery does not take place within four or five weeks there is usually a subsidence of the more acute symptoms, and the case is then characterised by a painless or nearly painless discharge, more or less profuse more or less purulent, which persists for weeks, perhaps months, often years, at times reduced to a mere secretion, which fastens the lips of the meatus together. This chronic form of urethritis is commonly known as gleet. 'Chronic urethral discharge means stricture. . . . I am quite well aware that well-defined stricture may be present without a palpable discharge; there is always to be found evidence of a certain degree of irritation present in all such cases, but there may be no appreciable discharge; when, however, there is discharge, there will in every case be found, if the examination is efficiently made, a well defined and unmistakable point of stricture. . . . The least contraction at any point in the urethral canal has been demonstrated as capable of causing the indefinite continuance of an urethral discharge, and even of establishing it, *de novo*, without venereal contact.' ('Urethral Discharges,' *New York Journal*, June, 1870. F. N. Otis, M.D.)

He then describes again his urethrometer and the mode of using it, and insists on the necessity for ascertaining in cases of stricture the normal calibre of the urethra in each particular case.

He again states the fact that the meatus urinarius is not a measure of the size of the normal canal, and refers to his deduction made some time ago from the examination of several hundred cases, 'that a constant relation exists between the urethral calibre and the size of the penis with which it is associated.' (See notice of 'Stricture of Male Urethra, its radical cure,' by F. N. Otis, M.D., *LONDON MEDICAL RECORD*, November 15, 1875). 'Whenever there is gleet in the sense of a chronic urethral oozing or discharge, an intelligent and thorough exploration with suitable instruments will invariably discover a distinct contraction of the meatus urinarius, or a readily recognised coarctation of the urethra at some point; and further, the complete restoration of the urethra to its normal calibre and suppleness at the contracted points will be required to warrant the statement that a permanent cure has been effected. The complete division of stricture has in my experience resulted uniformly in its complete disappearance within a period varying from three months to one year; and the cure of gleet has, as a rule, followed the complete division of stricture within a period varying from twenty-four hours to four weeks after the final operation.'

That treatment of gleet by a systematic introduction of sounds and bougies has often cured the discharge, 'no one will for a moment gainsay, but that it permanently removes the cause no one at this day is likely to affirm.

'For a permanent cure, a complete division of the contracting stricture must be made, and any treatment which falls short of this will, of necessity, fail in doing more than to temporarily remove the obstruction, which has been the cause of the gleet.'

Appended to the paper are statistical tables of fifty cases of gleet, or chronic urethral discharge, associated with urethral stricture. In all, the gleet had existed not less than several months. The ages varied from nineteen to sixty-eight years. The number of strictures per man varied from one at the

meatus to ten within a length of four inches and a-half. The fifty individuals presented a total of 137 strictures, including one case of five bands. Of the total number of strictures, twenty were found to be situated at the meatus, thirty-four in the course of the first inch from the meatus, twenty-three in the course of the second inch, twenty-nine in the course of the third inch, fifteen in the course of the fourth inch, eleven in the course of the fifth inch, and four in the course of the sixth inch. Analysing the causes, it may be seen that forty-eight cases were attributed to gonorrhœa; one was attributed to paraphimosis, and one to masturbation.

In one case only the stricture measured no. 8 French gauge. The rest varied from no. 16 to no. 37 Fr. Of the 137 strictures, 112 are stated to have varied from nos. 20 to 34, both included.

The normal calibre is given in forty-seven cases, and of these thirty-three measured from 30 to 32 Fr. The lowest was 28 Fr. and the highest 40 Fr.

The total number of operations on fifty cases was 101; twenty-one cases were operated on once; seventeen, twice; five, three times; two, four times; three, five times; one, eight times; and in one case the number of operations is not stated.

JOHN CROFT.

LEVIS ON A SUBSTITUTE FOR ESMARCH'S BANDAGE.—Dr. R. J. Levis, surgeon to the Pennsylvania Hospital, says, in the *Philadelphia Medical Times* of April 29, that he has for a long time discarded the use of the elastic webbing and constricting tubing, as proposed by Professor Esmarch, in favour of a bandage made of pure India-rubber. The bandage which he is in the habit of using for encasing the limb is five yards long and two and a half inches wide; and the constricting band or tourniquet is of a much thicker and stronger material, two yards in length and one inch and three-quarters in width. The pure India-rubber bandage has the merits of greater elasticity, strength, durability, cleanliness, cheapness, and more perfect adaptability. The constricting band is perfectly effective as a tourniquet, without the great disadvantage of the narrow tubing of Professor Esmarch in producing severe linear pressure, which has often caused more or less enduring paralysis from extreme nerve-compression. Dr. Levis's tourniquet-band is without chain and hook, the final securing being simply effected by tying together pieces of strong cord, one of which is permanently attached through a hole in each end.

WYETH ON THE SURGICAL ANATOMY OF THE ARTERIAL SUPPLY OF THE TIBIO-TARSAL REGION. In the *American Journal of Medical Sciences* for April, Dr. J. A. Wyeth, Assistant to the Professor of Anatomy in Belvedere Hospital Medical College, contributes an article on the surgical anatomy of the arteries of the tibio-tarsal region, with special reference to amputations at this part. Having commented on the statements of Gross, Erichsen, Leidy, and other surgeons and anatomists, he examines the results of eighty observations carefully made by himself, summing up as follows.

In 72 of 80 cases the posterior tibial artery bifurcated into the external and internal plantar, on a level with a line drawn from the most dependent portion of the internal malleolus to the middle of the heel's convexity. In 4 of 80 cases this bifurcation occurred a quarter of an inch below this point. In 4 of 80 cases it was half an inch below this point;

any variation from the usual point of division tending, in his experience, invariably downward.

Although anatomists give the arterial supply to the calcanean region (internal calcanean arteries) as coming from the posterior tibial artery (as shown in extracts given heretofore), the *résumé* of tabulated dissections shows that out of a total of 80 cases, in 38 there was not a single calcanean branch derived above the terminal bifurcation of the posterior tibial artery, while in all of these 80 dissections one or more good-sized calcanean arteries were derived from the external plantar within one and a quarter inches of its origin. In 80 cases the number of calcanean arteries derived from the posterior tibial was 51. In 80 cases 18 branches were derived opposite the point of bifurcation, and distributed to this region.

In 80 cases the number of calcanean arteries derived from the external plantar was 221, and every one of these was safely inside the line of incision in amputations at the ankle-joint, when that incision is not more than one-half inch posterior to the axis of the leg, with the foot at right angles to the leg. In all cases articular branches are derived either from the posterior tibial or internal plantar, or from both. In some exceptional cases the internal plantar gave off small branches to the heel.

The anterior flap is plentifully supplied in all instances by branches from the anterior tibial, especially the malleolar arteries.

The anterior and posterior peroneal distribute branches to the outer portion of the calcanean flap, those from the posterior anastomosing with the calcanean branches of the external plantar, and with those of the posterior tibial, when they are present. Dr. Wyeth does not think the branches from the peroneal arteries sufficiently large to supply blood enough to maintain the integrity of the calcanean flap, especially when their anastomoses are cut off by section of the posterior tibial, or of its plantar branches, too near their origin.

The relation of the posterior tibial artery is quite constant with the two muscles between which it runs; the flexor longus digitorum in front, and the flexor longus pollicis behind. The most reliable guide to this vessel is its pulsation, but in the event the tourniquet is applied, the thumb should be placed over the middle of a line drawn from the inner malleolus to the centre of the heel's convexity, while the four lesser toes are held still by an assistant; the surgeon moves the great toe, and marks the point at which he feels the tendon gliding under his thumb. The tendon of the longus digitorum is found in the same manner, and half-way between the two a curved incision, with its concavity towards the malleolus, will be over the artery. The relations of the veins on either side, and of the posterior tibial nerve behind, are among the least variable features of the anatomy of this region. In two cases he has seen the artery immediately behind the inner malleolus. When the posterior tibial is small, the peroneal branches undergo compensatory enlargement.

Dr. Wyeth has also made seven additional dissections of this region, with the following result.

In 4 out of 7 cases, calcanean branches originated from the posterior tibial artery—1, one inch; 1, one-half inch; and 2, one-eighth of an inch above the bifurcation. In 7 cases, 2 calcanean branches were derived opposite the bifurcation. In 7 cases, 19 calcanean branches were derived from the external plantar, within one inch of its origin; viz. 3, within

one-sixteenth; 2, within one-eighth; 1, within one-fourth; 4, within one-half; 4, within three-fourths; and 5 within one inch of the bifurcation. Articular branches were, as usual, from the posterior tibial and internal plantar. The posterior tibial bifurcated in every case, as usual.

BIGELOW ON EXCISION OF THE ELBOW-JOINT.—At a meeting of the Boston Society for Medical Improvement (*Boston Medical and Surgical Journal*, March 30) Dr. H. J. Bigelow related a case of caries of the elbow-joint, and made some special remarks on the mode of operation. It had occurred to Dr. Bigelow that if the condyles were not diseased, and could be safely left, and only the articulating surface of the humerus removed, the muscles attached to these condyles would remain undisturbed. The condition of the arm after operation would then approximate more nearly that of a case of excision described and figured by himself in 1867, wherein he had been able to strip the periosteum from the condyles without disturbing the muscles. The result was that the periosteum reproduced the condyles for muscular attachments, the flattened extremity of the humerus somewhat resembling a closed fist with the forefinger and little finger extended.

This was imitated in the present case by an operation as follows. After the median incision was made and the ulna cleaned, this bone was sawed partly through, about an inch and a half from the olecranon, and the section completed with forceps. The fragment being removed, the humerus could now be dislocated backward. The ulnar nerve was next drawn a little to one side, and the humerus sawed from the bed of this nerve obliquely into the olecranon depression, and similarly on the outside from the external condyle into the same depression.

The whole articulating surface was now readily broken out, leaving the condyles. The orbicular and lateral ligaments being now divided, the fore-arm was dislocated backwards, the radial extremity sawed off, and a few remaining points chipped out with gouge-forceps.

The result seemed an excellent one, and the wound was promising well, when the patient died from widely diffused embolism.

GATEWOOD ON THE TREATMENT OF GONORRHOEA.—Dr. W. K. Gatewood, of Jamaica, Virginia, writes in the *Virginia Medical Monthly*, that he uses the following treatment in cases of gonorrhœa, and that he has found it more satisfactory in its results than any other.

He orders the patient to take a saline cathartic every morning to keep his bowels in a good lax condition. He prepares for him a bottle of bicarbonate of potash, and arranges the dose so that he takes a drachm every day. An injection of twelve ounces of thin gum acacia mucilage is prepared, to which are added two drachms of carbolic acid. Sometimes the injection is weakened, when the inflammation is high. Dr. Gatewood always enjoins rest and a light diet, and positively prohibits all stimulating drinks, which advice is rarely ever followed. He always instructs the patient first to urinate, and then to wash the urethra out with tepid water before using the injection; to do this night and morning. If the case seem one of very high state of inflammation, and he can confine the patient to bed, he adds tartarised antimony to the potash, and uses water-dressings to the member. Since adopting this plan he never has

any dyspeptic symptoms, which follow often the use of balsam, yellow sandal, etc., and his patients get well much sooner, and at a much less cost. He treated ten cases last January, and all were cured perfectly in from eight to fifteen days, and on their feet all the time.

BATES ON THE TREATMENT OF FRACTURES BY THE BRAN-BOX.—Dr. A. Bates, of Viroqua, Iowa, calls attention (in the *Medical and Surgical Reporter*) to a mode of treatment for fractures, and other severe injuries of the leg and ankle, which he has successfully used, both in simple and compound fractures. A piece of inch board, long enough to reach from the upper part of the thigh to a little beyond the foot, about seven inches wide at the upper end, and five inches at the lower end, serves as the bottom of the box. A foot-board of the same thickness is nailed to the lower end, and two side pieces of thinner material, and at least seven inches wide, are firmly nailed to the bottom and foot-boards, and the box is complete. In applying it, a folded cloth should be laid in the upper end, and the bottom covered with unsifted corn meal an inch deep. The surgeon holding the limb by the knee and ankle, an assistant places the box beneath, and the limb is let down into it, so as to rest lightly on the meal, and held firmly while meal is poured in and compacted under and around it with the hands, assisted by a blunt wooden spatula, until the parts are immovable, soft cloths being placed between the thigh and the upper part of the box. Care must be taken that the meal is well compacted around the knee and ankle; indeed, the whole limb must be equally secured.

To prevent disturbance from involuntary movements of the patient, a small pad may be placed on the knee, and secured by a bandage passed around the outside of the box. A considerable amount of surface may be left uncovered, and remedies may be applied to the injured parts if it is deemed necessary. Dr. Bates has thought best to take the limb out of the box and wash it thoroughly, at least once a week; but perhaps all that is really necessary is to remove that part of the meal in contact with the skin, as often as it becomes saturated with perspiration, and this can be done, a part at a time, without moving the limb.

Some of the advantages said to be possessed by this method are the following. 1. The limb can be examined at any time without handling it. 2. The parts are immovable, and entirely at rest. 3. The circulation is not interfered with, since the pressure is not great, and is entirely even. 4. The dressing is more comfortable to the patient than any other that requires confinement to bed. 5. The material is cheap, and can be obtained almost anywhere. 6. The treatment is simple, and can be well applied by almost anyone.

Various modifications might be suggested to meet particular cases, but these will suggest themselves to the surgeon when occasion calls for them.

GALLOUPE AND GRAVES ON A CASE OF SLOUGHING OF THE SCROTUM; RECOVERY.—Drs. I. F. Galloupe and T. T. Graves relate the following case in the *Boston Medical and Surgical Journal* for June 29. On December 29, F. B., twenty-one years of age, and in good health, while at work near a revolving shaft moved by steam-power, had his apron and pantaloons caught and entirely torn off. On

examination it was found that the scrotum had been included with the clothing, and torn off entire as far as the inguinal canals; on the right side the wound extended somewhat higher than that point, the skin covering the penis was torn, and that of the perinæum stripped off back to the anus. The testes and spermatic cords were left uninjured, but completely uncovered.

It was thought best to replace the scrotum, hoping that a portion of it at least would not slough, which hope was not entirely disappointed. The only alternative seemed to be to remove the testicles, to do which all that would have been necessary would have been to cut the cords and secure the vessels. During the examination, and at the dressings subsequently, the testes were separated and laid upon the groins, to bring the wound of the perinæum the better into view. On the third day the scrotum had sloughed, except a piece about an inch and a-half square upon the left side of the penis. The entire wound was dressed with cotton-wool, soaked in an aqueous solution of carbolic acid, and no other dressing was used throughout the treatment. Healthy granulations soon covered the wound and testes; the spermatic cords began to shorten, and soon drew the testicles into contact with the external inguinal rings. The wound healed rapidly, the relic of the scrotum growing until the left testis was covered. The right one being still bare, it seemed as though it would be necessary to remove it. On examining the wound, however, on February 5 (the patient had not been seen for several days previously), it was found to have disappeared of its own accord, by escaping under the skin of the groin, and lay above the pubes, where it remained. The entire wound was healed on February 27.

BRIDGON ON EXCISION OF THE WRIST-JOINT FOR CARIES.—At the meeting of the New York Pathological Society on May 10, (*New York Medical Record*, June 10) Dr. Bridgon presented carious bones removed by the operation of excision of the wrist-joint. The patient was aged thirty-nine, a deaf-mute, married, a cooper by occupation, and of temperate habits.

A tumour made its appearance on the back of his right hand three years ago. It was painless, and grew slowly, and was probably ganglionic in character. It was subsequently removed by a cutting operation, and whilst recovering from the effects of this he fell and sprained his wrist; this was followed by swelling of the hand and forearm, which necessitated the use of incisions, which discharged for a long time. On admission into hospital on April 19, his general health was good. The right hand was swollen, the fingers extended, and incapable of motion. The concavity of the palm was effaced, and on its surface were the openings of two fistulous tracks communicating with carious bone. There was very slight motion at the wrist-joint, none at the metacarpo-phalangeal and phalangeal articulations; all the anatomical points were masked by hard brawny infiltration. It being believed that any partial removal of the bones involved would only lead to progressive destruction of the remainder, the operation devised and advised by Professor Lister of Edinburgh was proposed, and accepted by the patient.

On April 27, an incision was commenced over the middle of the back of the second metacarpal bone; it was carried upward in a line with that bone to the carpo-metacarpal articulation, and then midway

between the tendons of the thumb and index as high as the inferior border of the radius; the tendons of the thumb were drawn outwards, those of the common extensor inwards, the knife being kept in close contact with the bones. Then an incision was made on the inner border of the hand, reaching from two inches above the styloid process of the ulna to the middle of the metacarpal bone of the little finger; these incisions permitted all the soft parts to be separated from the bones on both palmar and dorsal surfaces, and gave abundant room for completing the subsequent steps of the operation, and in this dissection it was found that the os magnum had disappeared entirely, and that the contiguous bones were carious and more or less fused by ankylosis. All the carpal bones, the basis of the metacarpal, the inferior articulating surfaces of the radius and ulna, were removed; the cartilages of the latter were intact; but in consonance with the views of Lister, they were all carefully removed. No tendons were injured save those inserted into the carpal bones themselves, and after removal of Esmarch's bandage, which had been used during the operation, it was not found necessary to apply a single ligature.

On the 29th, carbolic acid irrigation was commenced. On August 10 everything had gone on remarkably well; the limb, or rather forearm, was one inch shorter than its fellow, and the parts involved were consolidating; the distance between the truncated radius and ulna and the metacarpal bones was about an inch and a quarter.

THE INTRA-ARTICULAR PRESSURE OF THE KNEE-JOINT: TREATMENT OF JOINT-DISEASE BY EXTENSION.—A writer in the *Dublin Medical Journal* for July says: Some interesting observations and experiments have, of late years, been made in reference to the intra-articular pressure of the knee-joint under different conditions, which have bearings of importance upon the physiology and pathology of that articulation, and may lead to practical suggestions of value. Amongst the most important are those of Bonnet, Reyher, and Ranke. The principal factors which these observers have taken into consideration, as modifying the above-mentioned pressure are—1. The position of the limb; 2. The condition of the peri-articular muscles; 3. The amount of intra-articular effusion; and 4. The traction to which the limb has been subjected. The position of the maximum capacity of the joint, which, of course, corresponds to that of minimum pressure, is the subject of some difference of opinion. While Bonnet asserts it to be that of flexion of the leg at an angle of 60° , the other two observers reduce the angle to 30° . The explanation of the discrepancy appears to be that Bonnet's observations were made upon dead bodies, in which the muscles were either removed or in the condition of complete relaxation which follows cadaveric rigidity; and that it is owing to the action of these (an element which he neglects to take into consideration) that the angle becomes changed. Ranke found that (taking the muscles into account) on starting with the attitude of complete extension, the pressure diminishes with the flexion of the leg, and attains its minimum at the angle named (30°). On further increasing the flexion the pressure increases rapidly, and becomes considerably greater than the primitive pressure corresponding to full extension, even before the leg has been flexed to a right angle. The contraction of the peri-articular muscles has considerable effect, according to the

measurements of Ranke (*Centralblatt für Chir.*, 1875), in augmenting and modifying the intra-articular pressure. Ranke was unable, from his observations, to establish any relation between the degree of pressure and the amount of intra-articular infusion; but, in individual cases, the law above-mentioned, as to the pressure in different attitudes of the limb, holds, whatever be the amount of effusion. The effect of permanent or continuous traction of the limb (as, e.g., by a weight or elastic force) upon the intra-articular pressure is modified by the other factors. By the expedient of forcing needles into the condyloid extremity of the femur and into the head of the tibia, Reyher (*Deut. Zeitsch. für Chir.*, 1873) has demonstrated ocularly that a moderate weight is capable of producing a veritable and measurable separation of the articular surfaces—a traction of 100 livres producing an elongation of $3\frac{1}{2}$ mm. He has further observed that, in cases where the quantity of synovia is normal or but very slightly augmented, the effect of continuous traction is to diminish the pressure within the joint. Paschen (*ibid.*) has already made the same experiments and observations with reference to the hip-joint. The effect is the same if the muscles be relaxed or paralysed, whatever be the amount of effusion. But if the quantity of effusion be considerable and the muscles active, the effect of extension by weight will be an increase of the pressure. Some of the applications of these observations to clinical and practical surgery are sufficiently obvious. They illustrate the slightly flexed attitude which the limb tends to assume in acute synovitis; but, above all, they indicate the rational employment of continuous extension ('la methode de distraction,' as it is termed) in those cases (of preference) in which inflammatory affections of the joint are attended with slight synovial effusion. Reyher would not, however, entirely reject the treatment of acute synovitis with effusion by this method, but would advise aspiration of the joint as a rational preliminary measure, after which it may be adopted in accordance with the principles here laid down. Morosoff (*Centralbl. für Chir.*, 1875) even goes so far as to assert that the light and uniform compression of the articular structures produced by traction in these last cases is useful. Another mechanical effect of traction upon the limb, and one which the last-mentioned observer more especially draws attention to in the case of the hip-joint, is of importance in reference to this plan of treatment—viz., the alteration of the points of contact of the articular surfaces, which, in the cases of both the hip and knee-joints, the different attitudes assumed by the limb under different degrees of force prove to take place. We may then enumerate these as amongst the various advantages claimed for the method of treatment of joint affections by extension; the modification of the intra-articular pressure; the diminution of the contraction of the peri-articular muscles; the alteration of the points of contact of the articular surfaces; and, finally, the rest and immobilisation of the articulation.

MATERIA MEDICA AND THERAPEUTICS.

HOLLIS ON THE TREATMENT OF EPILEPSY BY BROMIDE OF SODIUM.—Dr. W. A. Hollis (*British Medical Journal*, July 1, 1876) reports the effects of bromide of sodium in eleven well-marked cases of epilepsy, from which he concludes that there are some active therapeutic properties in the sodium salt.

As regards the females whose cases are described, Dr. Hollis carefully excluded pure hysteria, and in doubtful cases made use of a justifiable means of proof, which consisted in omitting the dose of the salt and substituting camphor water. In a case of this kind the fits were decreased in number from twelve in the fortnight to three in the two weeks, on returning to the sodium salt. The prognosis in some of Dr. Hollis's cases was apparently very unfavourable, yet the results of his treatment are extremely satisfactory.

For instance, in Case I., a boy aged fifteen, who had been the subject of fits since his birth, the attacks were kept in abeyance when the salt was administered in combination with a decoction of bark.

Case II., a male, aged twenty-two, who had been subject to epilepsy since an attack of sunstroke in Bombay, was free from fits during the continuance of the treatment with the salt, which extended over three months. One fit only occurred in five months, and this was subsequent to the cessation of the treatment.

In describing Case IV., a child, two years old, Dr. Hollis remarks that the bromides appear to exert a greater influence upon the so-called 'convulsions' of children than they do upon the more confirmed epilepsy of adult age, he having rarely found a case of such disease which did not speedily yield to small doses of these salts.

Case VI., a blacksmith, aged eighteen, had no return of the epilepsy during the five weeks he was under treatment.

Case VII. Although the fits in this girl were said to be due to a blow on the head, yet as far as the epilepsy was concerned, the treatment was very successful.

Dr. Hollis's paper is illustrated by a concise table, from which we abstract the following formulæ for the treatment of epilepsy by the bromide of sodium.

- (1) R Sodii Bromidi, gr. xv.—gr. xl.
Aquæ, vel Aquæ Camphoræ
vel Decocti Cinchonæ Pallidæ, ʒj.
ter die.
- (2) R Sodii Bromidi, gr. xv.—gr. xl.
Tinct. Cannabîs Indicæ ℥xv.
Aquæ ad ʒj.
ter die.
- (3) R Sodii bromidi, gr. iii.
Decoctæ Cinchonæ Pallidæ ad ʒij.
ter die.
(For a child, aged two years.)

[I. Economists have advocated the use of chloride of potassium in the treatment of this disease, and, proceeding onwards, we shall doubtless, ere long hear of chloride of sodium taking rank as a specific for epilepsy. We trust, however, that the good results recorded in this valuable contribution to therapeutics may strengthen the opinion that the value of bromide of potassium is due to the bromine and not to the potash contained in the salt.—*Rep.*]

H. SUTHERLAND, M.D.

GALLOIS AND HARDY ON THE CHEMISTRY AND PHYSIOLOGY OF MANÇONA BARK (ERYTHROPHLEUM GUINEENSE).—MM. N. Gallois and J. Hardy have published (*Archives de Physiologie*, May and June, 1876) an excellent article on this subject, of which the following is a short *résumé*. This bark is used by the natives of the West coast of Africa as a poison for their arrows; the tree from which it is obtained has been described by several naturalists, and is one of the Leguminosæ, sub-order Cæsalpinieæ; it grows to the height of about 90 feet, with a cylindrical trunk about 6 feet in diameter, and is called by the natives Tali or Teli. The wood is very hard, and much used for domestic purposes, as it escapes the attacks of white ants. The bark itself, which is used for poisoning arrows, and to make the test liquids for criminals, is usually in the shape of flattened irregular reddish pieces with roughened surfaces; it is hard, fibrous, inodorous, and causes violent sneezing when pulverised. It is said by travellers to cause the death of horses if chewed by them. Boiled with water it furnishes a red liquid, used by the natives as an emetic and purgative.

Experiments made with extracts of the bark and leaves on mammals and amphibia, show that both contain an actively poisonous principle, causing death in about 35 minutes. The symptoms produced were rapid and difficult respiration and anxiety, dilatation of the pupils, followed in a few minutes by the fall of the animal, convulsions and death. In the mammals the ventricles of the heart were found dilated and filled with the clot, the lungs engorged with blood and dotted with capillary hæmorrhages; the brain and cord healthy. In the amphibia, the ventricle was arrested in systole. In both, the contractility of the ventricles could not be excited by the galvanic current, although the other smooth and striped muscles retained their electro-contractility.

An active principle, to which the authors give the name of erythrophleïne, was obtained by them from the bark; they consider it to be alkaloidal. The substances obtained by two methods differed slightly from each other, one being a transparent amorphous matter, of a clear amber colour, and firm and gum-like to the touch; the other was of a yellowish-white colour, transparent, and crystalline.

The effects of these substances on animals were found to be analogous to the effects produced by the extract of the bark; moreover it was found that the

effect on the heart was the same, whether the poison was applied directly to that organ or came through the circulation.

Erythrophlæine is then a muscular poison; above all, a poison to the heart. Warm-blooded animals die immediately the heart is paralysed, but in frogs life persists during a variable time. A dose of $\frac{1}{2}$ to 1 milligramme placed directly on the heart, or 2 milligrammes injected under the skin of the foot, stops a frog's heart in five to eight minutes. A dose of 4 milligrammes injected under the skin of a rabbit kills it in some hours. Four centigrammes injected at intervals into the cellular tissue of a middle-sized dog, killed it in one and a-half hours, although it was curarised, without which probably death would have occurred sooner, as it would also probably if the dose had been given all at once. In warm-blooded animals, erythrophlæine produces convulsions and extreme dyspnoea, consequent upon the disturbance of hæmatisis; in cold-blooded animals it causes a progressive stupefaction, which goes as far as complete relaxation of the muscles, and during which death takes place. The muscles first impregnated by the poisonous fluid are the first to be paralysed; while those protracted by a ligature from its influence preserve their electro-contractility. The cardiac muscle is paralysed before the smooth and striped muscles, on account of the large quantity of poisoned blood which it receives. The effect is especially rapid when it is bathed directly by the solution, and then the organ becomes insensible to the electric current. In warm-blooded animals the heart on necropsy was always found soft and dilated, the contained blood giving the reactions of erythrophlæine. In frogs the heart's action became slower at first, and afterwards the ventricle stopped in systole, the auricles generally in diastole. In the dog the heart's action was increased up to the final period of poisoning, and in three dogs the arterial tension was raised after the administration of the drug. The double chloride of erythrophlæine and platinum acts exactly like erythrophlæine in causing the stoppage of the heart in the frog.

Atropine does not re-awaken the movements of the heart paralysed by erythrophlæine, nor does it prevent its action. Curare decidedly retards its effects. The leaves, seeds, and probably other parts of *Erythrophlæum coumanga*, an allied species, contain an alkaloid which acts like a poison to the heart, and which by its chemical composition approaches erythrophlæine, if it be not identical with it.

It is difficult to say whether *Mançona* bark is susceptible of therapeutic applications. Sternutatories have no longer their place in medicine, but it shares with digitalis, at first at least, the power of raising the arterial tension; and possibly if given in small doses its effects might be very different from those observed with the large doses given in these experiments. ROBERT SAUNDBY, M.B.

FOX ON THE TOPICAL USE OF BIBULOUS PAPER. At a meeting of the New York Medical Journal Association on May 19 (*New York Medical Record*, June 10) Dr. G. H. Fox read a paper on the topical use of thin bibulous paper in affections of the skin and mucous membranes. Two varieties of the paper were described: the French, or that used by dentists for absorbing the saliva while operating about the mouth; and the Japanese. The former was made of vegetable fibre containing an admixture of wool; could be easily reduced to a pulp by moisture; and

was capable of absorbing at least five times its weight of water. Its powers of absorption, perhaps, were no greater than those of good lint, but it absorbed far more rapidly. The Japanese paper, when moistened, was not reduced to a pulp, but could be rolled into cylinders, and then would resist a large amount of traction. It could, therefore, be rolled and made to enter sinuses, the urethra, etc., if desirable, and was sufficiently strong to permit its easy removal. Dr. Fox regarded the paper, more especially the French variety, as a cheap and convenient substitute for lint, cotton, or absorbent powders, and that it could be easily used in a goodly number of cases. It might be used for cleaning bleeding surfaces, and would make an excellent substitute for sponges, which are liable to convey the germs of disease from one person to another. In the treatment of the exuding forms of skin-disease, it was not regarded as of sufficient value to be worthy of recommendation. Its greatest value had been seen in the treatment of venereal disease, particularly genital sores. It had, however, served a very good purpose in the treatment of eczema of the breast occurring while nursing. The breast was simply covered with the paper, and frequently changed. When rolled into pellets of varying size, it formed a most admirable means for bringing fluid caustic substances into exact contact with the surface to be cauterised, and that surface only; for example, the application of nitric acid to the surface of a chancre. When the pellet had been used it could be thrown away, and transmission of the disease by means of instruments, etc., was readily avoided. It was said that the best dressing for venereal sores was that which kept the discharge most constantly absorbed. Lint and cotton might do that, but they were difficult to remove, and a powder would form a crust that would be objectionable. The spongy paper readily absorbed the discharge, and if frequently renewed, would keep the sore and surrounding parts clean without washing. As compared with lint, the paper was regarded as equal in every respect, and in many respects superior, because it absorbed a larger quantity and more readily, was easily removed, and cost only about one-fifth as much. The thin bibulous paper might be medicated, and specimens were exhibited medicated with fifty per cent. solution of carbolic acid; with persulphate and perchloride of iron, when it might be substituted for styptic cotton; with fifteen per cent. ethereal solution of iodoform, not specially recommended, however; with thymol, calingula, etc.

GRAY ON THE REDUCTION OF ANIMAL HEAT BY THE USE OF GELSEMIUM.—In an article on this subject in the *New York Medical Record* for June 10, Dr. G. H. Gray says that gelsemium is unrivalled as a febrifuge, and that he has never been disappointed in it as an agent for reducing temperature. He relates some cases in illustration.

He was called to see a child who had been listless constipated, without appetite, complaining of head ache and thirst for nearly a week. He was in bed with a coated tongue, very hot, dry, and rough skin flushed face, pulse 147, respiration over 40, and temperature 104°6'. Dr. Gray prepared a mixture consisting of ten drops of tincture of gelsemium, ten grains of bromide of potassium, and water half a small tumblerful, directing the mother to give a teaspoonful every hour, and afterward every two hours, until the fever began to subside, headache was re-

lieved, and free perspiration had appeared. This was about eight o'clock in the evening. Next morning, at nine o'clock, the child was playing out of doors. The bowels were constipated for four days, but with this exception there was not a sign left of any disturbance.

A severe case of typhoid fever, which occurred in his practice last summer, was treated with the same drug whenever there was a high temperature, with the effect of entirely breaking up the regularity of the morning and evening variations, and all through the third week of the disease keeping the heat below 101° .

In a case of perineal section for stricture, on the third day rigors set in, followed by the usual surgical fever, the pulse running up to 148, and temperature to 104° and a fraction. About seven o'clock in the evening the patient began taking the gelsemium, and at nine the next morning the pulse and temperature were nearly normal, the latter not reaching 100° . In a case of pleuro-pneumonia, between five o'clock in the evening and nine the next morning, the thermometer showed a reduction of the heat from 104.2° to 101.5° , due to the use of the same drug. In a case of scarlatina, between five o'clock in the evening and nine the next day, the temperature was reduced from 105° to 99.2° ; and during the whole disease, which lasted acutely only six days, the temperature never rose above 102° , except for a half day, when the gelsemium was stopped by mistake, then it rose to 103° , but was at once reduced to 101.8° by resuming the medicine.

For a child less than five years old, Dr. Gray usually prescribes tincture of gelsemium, twenty minims; bromide of potassium, twenty grains; water, four ounces; a teaspoonful to be taken every hour until fever begins to abate; then every two hours, until free perspiration is produced. For children from five to fourteen or fifteen, he gives in four ounces of water half a fluid drachm of the gelsemium and thirty grains of the bromide; for adults, a fluid drachm of the tincture, and a drachm of the bromide, to four ounces of water, with the same directions for taking.

The dose for a child is only about five-eighths of a drop, and the adult dose not two drops; and Dr. Gray thinks, as the full effects are obtained by these small frequent doses, the complaints that are made against the drug arise from too large doses. At all events, the effects above related are sufficient to claim for gelsemium the attention of all who wish to avail themselves of the best means of combating fever.

Lest some of the champions of bromide of potassium should say the above effects were due to that, instead of the gelsemium, he states that for some time he used the latter alone, with quite the same effect upon the temperature, and combined the two for the quieting effect of the salt, gelsemium not producing very marked results of that sort in such minute doses.

LAWSON ON THE THERAPEUTIC ACTION OF HYOSCYAMINE.—In the *Practitioner* for July, Dr. Robert Lawson, Assistant Medical Officer to the West Riding Lunatic Asylum, remarks that, in the fifth volume of the *West Riding Lunatic Asylum Medical Reports*, he published a series of observations on the physiological actions of the active principle of hyoscyamus. The effect on man of the administration of sufficient quantities of the drug

was shown to be the production of a subdued form of mania accompanied by almost complete paralysis of the voluntary muscles, and ending in quiet and refreshing sleep. The consideration of the character of the phenomena produced led to the hypothesis that, therapeutically, hyoscyamine might be useful in substituting for the extreme forms of excitement which accompany or result from many brain diseases, a quieter form of mania which, on disappearing in its turn, might leave the patient in a state of quiescence. In the present article he describes the effect produced by the drug in the treatment of recurrent, acute, and subacute mania, monomania of suspicion, and the excitement of senile dementia, setting aside till a future period the results of observations on the use of hyoscyamine in the epileptic status, the excitement of general paralysis, and other forms of cerebral disease. [Typical cases are given in illustration.]

One thing, he says, must be observed as characteristic of the use of hyoscyamine, that is, the potency and permanency of the action of individual doses. In these respects he does not think it is equalled by any other drug. In about fifteen minutes the most violent and excited patient can be thrown into a comparatively deep sleep by about one grain of the amorphous alkaloid, and on wakening from his his slumber almost invariably frees himself also from the delusions and hallucinations which have bewildered him; and he can adduce numerous instances in which this recovery, rapid as it has been in its accession, has also been thorough and enduring.

There is one class of cases of mania in which hyoscyamine is particularly useful. In the refractory wards of an asylum outbursts of excitement are constantly manifested which present more of the features of voluntary abandonment to angry passions than of pure insanity. Such patients are very aggressive, very loud in their denunciations, and very destructive of clothes and furniture. To such a patient a grain dose of hyoscyamine is a very ready and serviceable means of treatment. The violence and the alarming manifestations of muscular force which precede the administration of the medicine stand in very strong contrast with the helplessness, the absolute and conscious impotence, which follow shortly upon its exhibition. Many circumstances render such cases the most suitable ones for the use of the drug. Such patients are usually in robust health, have been eating well, and are not likely to suffer much from a temporary derangement of digestion, and none feel more keenly the inconvenience of being reduced to a state of helplessness. With patients suffering from acute or furious mania, however, the case is different. These not unfrequently are, when admitted, reduced to the last degree by the prolongation of extreme excitement, the loss of sleep, and the refusal of food. Their tongues and throats are generally dry, and the tube almost always requires to be resorted to for feeding purposes. In such cases, though hyoscyamine will produce a most certain and refreshing sleep, it will also by its physiological action increase the dryness of the throat, and thus both impede artificial feeding, and add to the constitutional disturbance, which, even in a moist state of the throat, the passing of the tube is apt to induce. But in numerous instances the use of hyoscyamine in outbursts of maniacal excitement has been productive, not only of great temporary benefit, but of highly satisfactory cures.

In epileptic excitement also the drug is productive of marked benefit.

In the treatment by hyoscyamine of acute, furious, or delirious mania, the drug possesses both great advantages and great disadvantages in such forms of derangement. The advantages are, the certainty of producing repose if a sufficiently large dose is administered, and the permanency of the effect produced, which is more marked after the employment of a single dose of hyoscyamine than after the isolated use of any other drug. The disadvantages are, that the dose required to combat extreme excitement may also be sufficient to produce such a physiological action on the heart and respiratory system as to cause danger to a frame wasted (as generally occurs in such cases) by prolonged fury, starvation, and loss of sleep. Also, the dryness of the throat following upon the use of the drug may interfere considerably with the success of forcible feeding, which forms so essential an element in the treatment of such cases. Combination with the tinctura pyrethri or some other equally powerful sialogogue may to some extent obviate this last disqualification. While mentioning the disadvantages associated with the administration of hyoscyamine, it is necessary to take note of the liability which patients only partially under the influence of the drug experience to the infliction of bruises. Before the physiological action of a full dose is completely established, and when it is passing off, the patient influenced by hallucinations of sight may rise, and while attempting to walk is liable, by the existence of partial motor paralysis and hypermetropia, to the infliction of bruises by contact with hard substances. This has to a certain extent been obviated by allowing a patient to sleep on a mattress placed on the floor. Dr. Lawson, however, has never seen any except the most trifling bruises produced, and certainly no contusions such as would almost certainly be inflicted by the amount of manual restraint necessary to meet the same excessive violence.

In chronic monomania of suspicion he has had very satisfactory results from the use of hyoscyamine. A large number of such cases result from alcoholism; and the delusions of suspicion remain as the chronic manifestations of the attack of *mania e potu*, which is generally found to have existed as the first appearance of mental derangement. In such cases the almost irremediable state of subdued suspicion is varied by exacerbations excited by the most trifling causes, sustained by hallucinations of all the special senses and characterised by extreme danger to the persons suspected by the patient. Not unfrequently such men lead lives of comparative indolence, inasmuch as the nature of their delusions frequently renders it unsafe to trust them with the implements required in any sort of labour. Being in addition well fed and compelled to take a fair amount of exercise they are generally sufficiently robust to enable them to bear well the temporary inconveniences of the hyoscyamine treatment.

With reference to the treatment of the excitement of senile dementia by hyoscyamine, it is only necessary to say that the benefit which has been long acknowledged as obtainable in that disorder from hyoscyamus itself naturally suggested the idea that the active principle might be still more useful. Consequently, the excitement of senile dementia was one of the first conditions in which Dr. Lawson employed the drug. The disadvantages, however, to which he has already referred in speaking of the treatment of

furious mania by large doses of hyoscyamine, apply equally to the use of the drug in senile excitement, and he has consequently found it advisable not to treat such cases with the active principle. In cases, however, which he has considered to be suitable for its administration, the arrest of the excitement has been very decided. In such cases he has given nutrient enemata from the commencement of the action of the drug, and for two or three of the following days.

No medicine capable of producing narcotism operates so quickly and with so much certainty, and none has such a decided capability of leading the mind from absorption in delusions and hallucinations through a milder physiological form of mania to a state of complete and, under favourable conditions, permanent quiescence. There is one form of disadvantage which arises not from the nature but from the mode of administration of the drug. If timid persons, instead of giving a full dose, say one grain, compromise matters by giving half a grain, the effect is that cerebral excitement without complete motor paralysis is produced and remains persistent through the whole period of the operation of the medicine. The following is the form in which hyoscyamine is administered:—Hyoscyamine, gr. j, Sp. Etheris, ℥viij, Alcoholis, ℥xxiv, Aq. font. ad 3j; M. ut fiat haustus. Dr. Lawson has not had occasion to use the drug hypodermically, and is not sure that the pungency of a concentrated form of this solution would not render a new formula necessary for subcutaneous use.

Dr. Lawson earnestly recommends hyoscyamine as *facile princeps* in the treatment of all cases of what may be called sthenic forms of mania, and especially in the aggressive outbursts of excitement which characterise life in a refractory ward, and in the treatment of chronic monomania of suspicion. He also suggests its use in some forms of disease regarding which observations cannot readily be made in a lunatic asylum. For instance, the constitutional effect on mucous membranes and the special effect on the urinary system suggest that hyoscyamine may be of service in gonorrhœa, and he has himself seen benefit produced by its administration in spasmodic stricture of the urethra. The dryness of the skin produced during the physiological action of the medicine suggested that it might be useful in colliquate sweatings.

EDWARDS ON THE TREATMENT OF NEUROSES DUE TO TOBACCO BY STRYCHNIA.—Dr. L. B. Edwards (*Virginia Medical Monthly*, quoted in the *Detroit Review of Medicine* for July), lays great stress on the use of strychnia in acute neuroses due to tobacco habit, especially cases marked by nervousness, muscular irritability, tremor, etc., the result of smoking. He mentions a case of acute shaking tremor of the hands, due to tobacco, in which he injected one-nineteenth of a grain of strychnia hypodermically. Within fifteen or twenty minutes thereafter the muscular control of the hand, on the side in which the injection was made, was nearly perfect, and the general nervousness was perceptibly modified.

STUART ON THE ACTION OF BICARBONATE OF POTASH.—In a letter in the *Students' Journal*, July 28, 1876, Mr. J. A. Erskine Stuart says: 'Bicarbonate of potash is stated in our various textbooks to be antacid, antilithic, antarthritic, diuretic, and alterative. But, besides these, it possesses a very peculiar property, which I have seen mentioned

in no work on *materia medica*. If taken in a large dose, as a drachm, it produces anæsthesia in different parts of the body. One day lately I took about a drachm, and a few minutes afterwards I felt a peculiar numbness all over the cheeks and round the lips. This numbness lasts for a considerable time. It has also been observed in the limbs and trunk. This peculiar action may account in some cases for the immediate relief which this drug gives in acute rheumatism, the diuretic, antacid, and anæsthetic properties all combining to assist in the relief from pain.

W. DOUGLAS HEMMING.

SMITH ON THE TREATMENT OF BURNS.—Dr. Q. C. Smith extols, in the *Pacific Medical and Surgical Journal*, the following dressing as the best for burns.

Mix subnitrate of bismuth with pure honey until it forms a thick paste. Spread the mixture plentifully over the burned surface and the parts near adjoining as soon as possible after the burn occurs. Then cover the parts thickly with cotton-wool wadding and bind closely. In the majority of cases this dressing should not be removed for three or five days, when the parts should be immersed in water until the dressing is very soft and easily removed. The same dressing should be immediately renewed.

TOXICOLOGY.

MARMÉ ON THE POISONOUS ACTION OF ARSENIOUS ACID AND OF ARSENIC ACID.—In the *Nachrichten von der Königl. Gesellschaft der Wissenschaften*, Göttingen, nos. 22, 23, 24, 1875, is an account of some comparative experiments by M. Marmé, on the poisonous action of arsenious acid and of arsenic acid. Doses of the two acids containing equal amounts of arsenic (or with a little more in the arsenic acid dose), and diluted with water, were given to animals as similar as possible in age, weight, etc., being introduced directly into the circulation, or into the stomach, or the connective tissue. The symptoms are detailed. Without exception, the doses of arsenious acid proved more rapidly fatal than those of arsenic acid. The acid salts behaved similarly to the free acids. The fact is against Munck and Leyden's view, that arsenious acid in the blood is oxidised to arsenic acid, and that only as such it dissolves the blood-corpuscles, and causes fattening of various tissues and organs. The authors think it probable that when arsenic acid is introduced into the blood it is reduced to arsenious acid, and therefore its action appears more slowly. They further describe some experiments on the use of toxic substances to counteract poisoning by arsenic acid.

HOLLEY ON POISONING BY OIL OF RED CEDAR.—In the *Detroit Review of Medicine and Pharmacy* for July, Dr. D. C. Holley, of Vernon, Michigan, relates a case of poisoning by oil of red cedar (*Oleum Juniperi Virginianæ*). Mrs. W., wife of a farmer, supposing herself *enceinte*, swallowed half an ounce of oil of red cedar about ten o'clock at night, for the purpose of producing abortion. A few minutes after going to bed, she told her husband she felt very strangely; her eyes to her felt as if bursting from their sockets, and her head as if enclosed with an iron band. A slight attempt at emesis ensued, and a very little of the oil was vomited; twitching

of the muscles was observed, and in a few moments more a most violent convulsion came on, and all further consciousness on her part for the next twelve hours was lost. Convulsion succeeded convulsion in rapid succession, until within two hours she had eleven. Dr. Holley was summoned about one and a-half hours after the poison was taken. He gave immediately an emetic of sulphate of zinc and ipecacuanha. Free vomiting quickly ensued, and a portion of the oil came up with the contents of the stomach, as evidenced by its characteristic odour and the oil floating on the surface of the matter ejected. There was only a slight abatement, however, in the rapidity of the recurrence of the convulsions—none whatever in their violence. As soon as the action of the emetic subsided, he administered chloral hydrate and bromide of potassium, each twenty grains, in cinnamon water. Sinapisms were applied to the nucha, feet, and epigastrium.

The convulsions now ceased and did not return; the chloral and bromide were continued, however, once in two hours, in doses of ten grains each for the remainder of the night. She lay apparently in a deep comatose sleep until about nine o'clock the next day, when she awoke to perfect consciousness with no recollection of what had occurred since swallowing the oil. She made a good recovery. So far as the pregnancy was concerned, it probably did not exist in the case at all, as there was no evidence of abortion or of any uterine action.

OBSTETRICS AND GYNÆCOLOGY.

GUÉRIN ON THE DIFFERENTIAL DIAGNOSIS BETWEEN MORBID PELVIC CONGESTION, PHYSIOLOGICAL CONGESTION, AND METRITIS.—In lectures published in *L'Union Médicale* (summarised in *Paris Médical*, May 18, 1876), M. Guérin indicates the symptoms of the above various normal or pathological states, and the means for distinguishing them. The physiological congestion of menstruation has for its certain characteristic its regularity and its duration, which varies from two to three days. In pathological congestion the hæmorrhage comes at the end of fifteen days, or three weeks; it shows itself at irregular intervals, and lasts from two to fifteen days, three weeks, or even more. When the catamenial congestion is the cause of the morbid congestion, the sanguineous discharge which accompanies it assumes at first characteristics of irregularity and of duration. At length the phenomena peculiar to one or other of these congestions, increase in the size of the uterus, sensations of cramp, of weight, etc., disappear with the sanguineous discharge in menstruation, whilst they remain in pathological congestion. On the other hand, we distinguish morbid congestion from metritis by the following characters: the leucorrhœa which accompanies congestion consists of a transparent, opaline mucous, while it is yellowish, muco-purulent, or purulent in inflammation. More than this, in congestion the patient experiences a sensation of a heavy body in the pelvis which tends to come out, and of dragging in the groins; the vaginal walls present a

peculiar œdematous sensation. It is very rare that the uterine neck becomes affected with ulceration, and the uterus still present some mobility. In metritis the patients do not experience this sensation of a heavy body trying to escape; the uterus is less mobile, more fixed. The pains are more acute, radiating towards the anal region; the uterus has a firmer consistence, and ulcerations of the neck are frequent. Uterine fluxion is only a degree of congestion; it does not exist as a separate morbid entity, and therefore there is no reason for giving the diagnosis between the two affections.

W. DOUGLAS HEMMING.

HUMPHREYS AND FENNER ON A CASE OF SEPTUM OF THE VAGINA.—Drs. Humphreys and Fenner, of Seguin, Texas, report to the *American Supplement of The Obstetrical Journal of Great Britain and Ireland*, for May, 1866, a case of a complete septum of the vagina. The patient, a German lady, aged nineteen, stout and plump, was taken in labour on January 11. They saw her four days afterwards. She was greatly fatigued, but not exhausted. The head rested above the brim, was in good position, the occiput to the left, and was freely movable. The os tincae, dilated to about half the full size, covered the right parietal bone. They changed her position, and presently found the os covering the left parietal bone, and it was some little time before they noticed that there were two vaginae and two mouths to the womb, with the head resting centrally and heavily against the septum.

The two passages were exactly similar in every respect, and it was clearly impossible to deliver the child through either. They decided to cut the septum, although they could recollect no authority or precedent for it. The head was pushed back, two fingers passed between it and the septum, a curved probe-pointed bistoury, carefully guarded, was used, and the septum divided about an inch. A few pains brought the head against the septum, when another inch was cut, and so on until the septum was cut through and the child expelled by the natural efforts. The hæmorrhage from the cut was only an ounce or two, and the woman recovered promptly and without a bad symptom. The child, apparently dead, was revived after long efforts.

The septum was placed antero-posteriorly, commencing at the arch of the os pubis, passing down to the fourchette with a free edge, flush with the labia minora, and attached to the perinæum, the walls of the vagina, and the lips of the os uteri, holding the latter nearly in contact. It was about $1\frac{3}{4}$ inches wide. Its free border in front was almost a feather-edge. Higher up it was of uniform thickness, of about $1\frac{1}{2}$ lines in the centre, growing thicker each way to its junction with the vaginal walls. Under the knife it had a fibrous feel, as if composed of sewing-threads. The part between the lips of the uterus was spread out a half-inch wide, either naturally or by the long-continued pressure of the head.

REPORTS OF FOREIGN SOCIETIES.

ACADEMY OF MEDICINE IN PARIS.

June 13. *Liqueurs*.—M. Decaisne read a memoir on the liqueurs Grand Chartreuse and Eau de Mélisse des Carmés, in reference to alcoholism. He came to the conclusion that the plants which enter into the composition of these liqueurs were identical with those used in the manufacture of absinthe. They all contain essential oils of a more or less dangerous character. Thus in equal doses, the effects of these three liqueurs are identical and produced the same variety of alcoholism. These affirmations were not, however, supported by any proofs, and did not provoke any discussion.

June 20. *Sphirophore*.—M. Woillez read a memoir on the sphirophore, an apparatus intended for the treatment of asphyxia, especially that of drowning persons and new-born children. It is composed of a cylinder of sheet iron closed on one side and open on the other, and large enough to contain the body of the person asphyxiated, who is put into it up to the head, which remains outside. A diaphragm afterwards closes the opening round the neck. An air-bellows placed outside the case, but communicating with it by a tube, is set in motion by a lever, of which the lowering produces the aspiration of the air confined round the body; the raising of the lever drives back into the case the air which had been abstracted from it. If a dead body were experimented on, which M. Woillez had done, every time the lever of the air-pump was lowered, the air was seen to enter the chest, of which the walls rose as in life, whilst everything resumed its place when the lever was raised. Each movement introduced from half a litre to a litre of air into the lung. It is easy from this experiment to deduce the utility of the sphirophore in the treatment of the asphyxia of drowned persons, and of new-born infants. The use of the instrument is perfectly safe; it never produces the slightest pulmonary lesion.—M. Depaul affirmed that for new-born infants at least, the means usually employed, notably mouth-to-mouth insufflation, or insufflation by the help of the laryngeal sound are amply sufficient. Insufflation sometimes induced positive resurrection.

June 27. *Seat of the Murmur in Pregnancy*.—M.

Depaul brought to mind the origin of this discussion. M. Glénard, junior (of Lyons), localised the murmur of pregnancy in the epigastric artery. M. Bouillaud especially placed it in the external iliac artery. M. Depaul summarised the different theories formulated on the mechanism of this murmur from the moment of its discovery by M. Kergaradec up to the present time, compression of the veins of the minor pelvis, uterine arteries, communication with the placental veins, etc. The theory which placed the seat of the murmur of pregnancy in the epigastric artery was not new. According to a communication addressed to M. Depaul by M. Stolz, there exists a paper by Kiwisch dating from 1849, in which all the facts and all the ideas contained in M. Glénard's memoir are to be found. However, the latter, according to a letter addressed to M. Depaul, renounced the theory of the seat of the murmur in the epigastric artery and located it in an anastomotic branch between the internal iliac and the ovarian arteries—a large artery to which he proposed to give the name of puerperal artery. M. Depaul did not deny the possibility of a *bruit de souffle* in the epigastric artery, but it could not be a *souffle* comparable to that of pregnancy, which, according to M. Depaul, was seated only in the uterine arteries, which were largely developed during the course of pregnancy. Neither the theory of the epigastric murmur, nor that of M. Bouillaud, which placed it in the large iliac arteries, explained how this murmur might be heard from the end of the third month of pregnancy, when the uterus had not yet passed beyond the brim of the pelvis and could not consequently compress the epigastric artery nor the internal iliac. Besides, this murmur was not only heard in pregnant women, but several hours, and even several days after delivery. Finally, Dr. Rapin, of Lausanne, had shown in a decisive manner that the murmur was seated in the uterus. If the finger were introduced into the neck of the uterus of a pregnant woman, all accoucheurs knew that strong pulsations like those of a large artery were felt on the internal surface of the organ. If this uterine artery were compressed, at the moment the stethoscope was applied to the abdomen, the murmur disappeared. M. Depaul regretted not to be able up to the present time to furnish absolute proof of his theory by direct auscultation of the uterus exposed by the Cæsarean operation.

July 8.—M. Depaul, continuing the reading of his paper, combatted M. Bouillaud's theory, attributing the murmur to the compression of the iliac artery. There were radical differences between the murmur of pregnancy and that obtained by compressing an artery—the crural, for instance. In this, there was rather a pulsation with a murmur, whilst the murmur of pregnancy was simple, exempt from all pulsation, very different from the murmur with pulsation found where there was no pregnancy, in cases of uterine tumour compressing the arteries. It was necessary in pregnant women to distinguish the true uterine murmur from the compression-murmurs. The murmur of pregnancy was characterised by the absence of pulsation; it was almost constantly intermittent, and only appeared continuous when the heart-beats of the mother reached or exceeded 120. It began to be heard in the course of the third month; it was very superficial. It apparently and really passed under the ear, since it was produced in the uterine wall, which was only separated from the ear by the abdominal wall. The murmur of

the external iliac was deeper. The uterine murmur was more diffused than the iliac murmur; it was perceptible throughout the whole extent of the abdominal wall in contact with the uterine wall; it disappeared when the uterine wall was compressed by the stethoscope. The bruit of the uterine murmur was due to the enlargement of the uterine vessels during pregnancy, whence arose a larger size of those vessels than that of the trunks whence they spring. The arterial blood thus passed from narrower to wider canals; hence arose the murmur.

Causes of the Fermentation of Urine.—M. Pasteur read a memoir in conjunction with M. Joubert, on the causes of the fermentation of urine. Alkaline fermentation of the urine or transformation of the urea into carbonate of ammonia; in the first instance attributed to the action of the vesical mucus transforming itself into a ferment under the influence of the oxygen in the air; was referred by M. Pasteur in 1862 to a minute microscopic vegetable growth. Recently, M. Musculus, of Strasburg, announced that in cases of catarrh of the bladder he had obtained from urine a substance precipitated by alcohol, soluble in water, transforming urea into carbonate of ammonia, as diastase transformed starch into dextrine and glycose. M. Pasteur believed that this ferment, far from being a direct derivative of the vesical mucus, was a product of the minute microscopic vegetable growth pointed out by him. It would be the only example of an organic ferment giving birth to a soluble substance, capable of determining the same fermentation as that engendered by the microscopic creature. It was all the more important to prevent this microphyte from penetrating into the bladder and to destroy it there. Carbolic acid had no action on it; solution of boracic acid seemed to arrest its development.

ACADEMY OF SCIENCES.

May 22. *Chloral*.—M. Oré reported a case of traumatic tetanus, cured by intravenous injection of chloral. The injections were made from June 23 up to July 26, 1875, and the total quantity of chloral injected was 56 grammes. M. Alarco, of Lima, who obtained the cure, considered himself to be the first person who had ever treated tetanus in this way. M. Oré pointed out that his own cases occurred much before this.

Thermo-cautery.—M. Guérard, jun., having claimed the priority of the thermo-cautery presented by M. Paquelin, M. Gosselin pointed out the differences between this instrument and the one proposed by M. Guérard.

May 29. *Muscular Contraction*.—MM. Morat and Toussaint presented a memoir on the variations of the electric condition of the muscles in voluntary contraction and in artificial tetanus, studied by the aid of the galvanoscopic *patte*. A first result of these experiments was that the induced contraction, brought on by voluntary action, depended on the suddenness only and not on the strength or the duration of the contraction. With regard to tetanus they had observed the following facts. Tetanus artificially brought on by interrupted currents, comprised two types, separated by a number of intermediate conditions. In one of these types, tetanus made up of short shocks and relatively few shocks, the oscillations of the electric condition were still sudden and of a certain amplitude.

In the second type (tetanus made up of long and numerous shocks) the muscular current remained in almost constant negative variety. The oscillations of the electric state of the muscle, being very little accentuated, did not provoke more reaction in the galvanoscopic *pilule*. It was only when the negative variation established itself; that is to say, at the very moment when the inductor tetanus began that the nerve of the induced *pilule* could be excited. Applied to the study of voluntary contraction, these data proved that the permanency of the negative variation indicated by the galvanometer was only exclusively due to the inertia of the apparatus, but represented at least partially a real phenomenon. There was every reason to believe that a very mobile apparatus would give analogous indications.

Tactile Sensation.—A note on tactile sensation by M. L. Lalanne was read. Imitating Lissajous' method of determining the duration of visual sensation, he endeavoured, in concert with MM. Ch. Martin and Aug. Le Pileur, to discover with what rapidity an object in contact with the skin must be turned, for the repeated frictions to give a continuous sensation. The results of thirty-three experiments were as follows. 1. Continuity is never manifested for less than ten rotations to the second. The duration of the tactile sensation observed did not then surpass one-tenth of a second, and in a certain number of experiments was less. 2. The least duration observed was from one twenty-fourth to one twenty-fifth of a second. 3. This minimum of duration varied with the individuals, and according to the parts of the body. A personal equation, analogous to that of which the astronomers are obliged to keep account, gave a variable quantity between one-tenth and one-fourteenth of a second for the persistence of the sensation, according to the observers; contact having occurred on the dorsal surface of the second articulation of the index finger. On the external part of the arm, between the deltoid and the elbow-joint, the duration, according to one of the observers, was rather more than one-thirteenth of a second, whilst according to another, it descended almost to one-twentieth of a second. The course of these researches had been interrupted, and the dispersion of the three co-workers who undertook them prevented their being resumed.

The Action of Digitalis.—MM. V. Feltz and E. Ritter communicated the researches they had made after M. Bouillaud's indications, on the subject of the action of digitalis in comparison with that of the biliary salts, on the pulse, arterial tension, respiration and temperature. A. By the biliary salts and the infusion of digitalis (one part in 100) administered in non-poisonous doses, the temperature is lowered about one degree for the two substances; the arterial tension falls from two to three centimètres of mercury for the biliary salts, and from six to seven centimètres for digitalis; respiration becomes irregular in both cases without any grand departure from the normal condition; the pulse is lowered under the influence of the two poisons. The only observable difference is that with digitalis the extreme descent lasts a very short time, and is followed by an acceleration which may last for twenty-four hours; with the biliary salts, the diminution of the number of pulsations lasts a longer time, but is not followed by abnormal quickness. Animals placed under the influence of biliary salts lose less weight than those which are digitalised. In the former the diminution does not exceed

300 grammes, and reaches more than 100 grammes in the second. After section of the pneumogastric and the sympathetic nerves the pulse is still influenced by biliary salts and digitalis in the first case, and by no means in the second; the temperature and the respiration continue to act in the same way. B. For the poisonous doses, the cases of biliary poisoning in which death does not occur for some hours, can only be compared with those in which digitalis is administered in large doses. In animals which die by biliary poisoning, the temperature and the pulse decline regularly until death occurs; the morphological changes in the blood and the hæmorrhages which are the result may thus be seen. In dogs digitalised to the extent of four cubic centimètres of infusion to every kilogramme of their weight, the temperature falls progressively and very regularly from seven to eight degrees; the pulsations diminish after more or less strong oscillations to the half of their normal amount. The arterial tension declines, and falls as low as three centimètres of the mercury. Sometimes sudden death takes place in cases of digitalisation. This always supervenes at a time when the pulse is very rapid and very feeble, without any warning of the death-struggle from the diminution of the arterial tension and the temperature. No chemical or morphological changes in the blood are ever observed. C. As the pulse does not fall in digitalised animals after the section of the pneumogastric and sympathetic nerves, as is the case in animals poisoned by biliary salts; as the blood does not show any change comparable to that pointed out and demonstrated in poisoning by bile; the action on the muscular tissue, whether curarised or not, not being the same in both cases, it may be concluded that the effect of digitalis is much more powerful over the nervous system than over the blood or the muscular tissue, as it occurs with the biliary salts. The nature of the death resulting likewise tends to establish this difference, for, in all the necropsies of animals killed by digitalis, the head was found in a state of relaxation, containing as nearly as possible the same quantity of blood in each ventricle. The heart was never found in a state of tetanic contraction, which is the rule in biliary poisoning; and, whenever MM. Feltz and Ritter had the opportunity of examining the heart shortly after death, they were able to prove by the electric pile that the cardiac muscle had not lost its contractility.

June 12. *Glycæmia.*—M. A. Bernard continued his communications on glycæmia. To demonstrate the presence of sugar in the blood, the albuminous matters must first be disengaged; after which all the physical, chemical, and organoleptic methods will show the sugar. In general it will suffice to boil the blood with an equal quantity of sulphate of soda, to subsequently obtain the characteristic reaction with Fehling's liquid. The titrated solution is used.

Treatment of Sympathetic Ophthalmia.—M. Boucheron submitted to the judgment of the Academy a memoir on the section of the ciliary nerves and the optic nerve at the back of the eye, substituted for the enucleation of the eyeball, in the treatment of sympathetic ophthalmia.

Sugar in the Blood.—M. Claude Bernard demonstrates that the sugar of the blood becomes rapidly destroyed after its extraction from the vessels. Acetic acid is the substance which has the power of retarding this decomposition. The disappearance

of the sugar after death takes place in a gradual manner, which is so much the more rapid as the proportions become smaller. It also results from numerous experiments, that, in the living animal, the richness of the blood in sugar is subject to frequent oscillations.

The Plague.—M. Tholozan forwarded a note on the plague in Mesopotamia, in 1876. He showed that in the preceding epidemics, the plague spread from place to place, from the autumn to the time of the great heats. He mentioned quarantine as the best way of preventing the spread of plague germs.

The Movements of the Brain.—M. Salathé sent a paper on the graphic study of the movements of the brain. He had obtained the following results. 1. The oscillations of the liquid in relation to the respiration, weak and sometimes *nil* in calm respiration, become very marked in efforts, exclamations, etc. 2. The respiratory oscillations observed simultaneously at the cranium and the spine are synchronous. 3. Artificial respiration reverses the order of the oscillations, the liquid then rising on inspiration, lowering at expiration. 4. Oscillations depending on the cardiac systole, which may be partly or completely masked in the case of increased respiration, give a tracing resembling that of the pulse. 5. Position exercises a great influence over the intracranial pressure, which indicates considerable changes of the level of the liquid, which rises notably when the tail of the animal is raised, and falls when the contrary is effected. 6. Anæsthetics may modify the phenomena in two ways, either by suddenly putting a stop to the respiration, and consequently to the oscillations which depend on it, whether by suppressing the latter, and regulating the respiration.

Preserved Meats.—M. J. Pagliari submitted several specimens of meat preserved by a ferruginous solution, together with a bottle of the liquid used for preserving it.

July 3. *The Blood in Anæmia.*—M. Vulpian, in the name of M. Hayem, presented a memoir on the anatomical characteristics of blood in anæmic subjects. The size of the corpuscles is modified in a remarkable manner. Many are found which are much larger, but much thinner than in the normal condition, whilst the major part are smaller than the smallest normal corpuscles. The shape is more or less changed, especially in the medium and small corpuscles. The colour is deeper than in the normal condition.

Anæsthesia by Intervenuous Injection of Chloral.—M. Linhart, a surgeon in the Austrian navy, communicated a case of anæsthesia by intravenous injection of chloral in order to reduce a fracture of the humerus. Seven grammes of chloral were injected in fourteen minutes. Anæsthesia lasted for half an hour without sickness or any accident whatsoever.

REVIEWS.

A Treatise on the Diseases of the Nervous System. By WILLIAM A. HAMMOND, M.D., Professor of Diseases of the Mind and Nervous System in the Medical Department of the University of the City of New York, etc. With one hundred and nine Illustrations. Sixth Edition, Re-written, Enlarged, and Improved. New York: D. Appleton and Co. 1876.

It is most gratifying to find so earnest and practical a physician as Dr. Hammond giving to us his large experience, gained by a life's labour, in this comprehensive volume on the diseases of the nervous system; and we should be wanting in courtesy did we fail to congratulate him upon the good and solid work he has accomplished.

If it claims pre-eminence in any one respect, it does so in the fact that it is essentially practical; and in passing from page to page one recognises at once the outcome of thoughtful and honest work. Dr. Hammond has not been led away by the mere researches even of the greatest physiologists, but he has compared their assertions with his clinical and pathological data, and expressed his opinions based upon a matured experience. Neither does he fail to give credit where it is due for originality of investigation—his pages are embellished with references to the most learned neurologists of the present century. In all probability Dr. Hammond is of opinion that minutiae of detail even to repetition is essential for a clear statement of his views—and although in this we cannot altogether disagree with him, yet perhaps we speak advisedly when we suggest that in the future it would be well rather to pare down in order to admit new material than to increase the bulk of the present volume.

It is extremely interesting to observe the implicit faith which Dr. Hammond has in the effect of remedial agents for the curative treatment of nervous disorders. We say nothing more than this—that we hope other practitioners are equally successful. The writer, however, has found from an extensive experience, that with a carefully regulated diet, rest, soothing influences, and general hygienic measures to promote due elimination of waste products, many of Dr. Hammond's vaunted specifics can be advantageously dispensed with.

It is to be regretted that Dr. Hammond, in his clinique, fails generally to give the age of the patient; and it is also an omission of great importance that the diathesis and temperament appear to be ignored, and in very few cases do we find the condition of the urine noted.

For the complete study of nervous disorders there are four points of prime practical importance to be considered, namely, age, diathesis or constitution, and the nature of secretions and excretions, but particularly that of the urine. This will often enable us to come to a more definite prognosis than the use of the æsthesiometer or the ophthalmoscope.

There are many temporary pareses due to thromboses of either brain or cord, coexistent with copious albuminuria, which pass off in direct ratio as the albumen disappears. Dr. Hammond does not seem to have noted this. Such a condition applies equally to the psychical as it does to the physical part of our organisation.

The chief points which neurologists have now-a-days to study are those which refer more immediately to degenerative changes of the connective tissue of nerve-matter. That this comes to be a question of nutrition is clear, yet it must be understood that the nutritive processes are functionally altered from the non-elimination of waste products, rather than from (as many observers would have us believe) arterial change. But it must be apparent that the cause produces an effect equally and probably simultaneously upon the vascular and upon the nervous systems. Chronic nervous diseases are

more due in the first place to the condition of the blood than to its supply.

Dr. Hammond first discusses cerebral congestion, cerebral anæmia, and cerebral hæmorrhage. He divides congestion into active and passive; and he recognises six varieties, namely, the apoplectic, the paralytic, the convulsive, the soporific, the maniacal, and the aphasic. Concerning passive cerebral congestion, our experience is not quite in accord with Dr. Hammond's, for the signs and symptoms which he lays down as indicative rather incline one to the opinion that the cases described are due to defective nutrition, impoverished blood, and vaso-motor deficiency, and that capillary thrombosis is of much more frequent occurrence in association with miliary aneurisms than with what Dr. Hammond would have us to understand as mere passive congestion.

When we have passive engorgement of cerebral veins and sinuses from cardiac dilatation, for instance, we have not, as a rule, even functional derangement of either motor or psychic centres.

The chapter on cerebral hæmorrhage is not arranged with that regularity and definiteness which would cause its meaning to be easily grasped by the general reader. Upon first going over it, we thought it not to be compared with the other articles, but upon second observation we found that the matter, although somewhat discursive, was complete in its way. It is true that the signs of hæmorrhage into the anterior lobe are negative rather than positive, yet some more notice ought to have been taken of this condition. It would also have been as interesting as it is important to have some physiological explanation of the objective and subjective signs produced by definite gross lesions; also the signs of hæmorrhage into the upper or lower, or inner or outer, part of the pons Varolii might have been well discussed, and the same remark applies to the crura.

Of the existence of paralysis on the same side as the brain lesion, Dr. Hammond perhaps wisely says little. He rests satisfied with Longet's assertion, that it is explained by the fact that the decussation of the anterior columns of the cord is imperfect. However this may be, Dr. Brown-Séquard's theory of inhibition is certainly the most feasible. For our part, we believe that such cases, if they do occur (and it is hard to doubt the authority of some good observers), are very rare. From over 1,000 cases of paralysis, and from 473 *post mortem* examinations of brain-lesions, we have never yet been able to verify the statement.

Now and again we hear of extensive hæmorrhage into one lateral half of the brain with paralysis of the same side, and perfect freedom of the opposite. We are so far sceptical on the point as to disbelieve that such a condition ever existed.

Dr. Hammond agrees with Dr. Flint in saying that there is no especial apoplectic constitution; but we cannot assent to this, for the truly apoplectic has a physique and a diathesis as strongly marked as that of the consumptive.

On the treatment of cerebral hæmorrhage, Dr. Hammond expresses the same opinion as most authors, and is in accord with the experience of the present day. But we are surprised to find that, although he recommends the use of the continuous current to the head in cases of cerebral congestion, he does not refer to this form of treatment in the cerebral depression consequent upon cerebral hæmorrhage. We know that in many cases it has in our own hands

saved the lives of patients where progressive hæmorrhage has been going on for days, and apparently profound coma with stertorous breathing has set in; and where there has been complete insensibility and absence of any automatic movement. In these, the application of the continuous current to the lower limbs has roused the patients from unconsciousness to positive volitional sensibility, and by the administration of nourishment death has been averted. We could, if space permitted, quote many such cases.

In the symptomatology of cerebral meningeal hæmorrhage, we find want of definition. For instance, it is stated that it does not differ from severe forms of cerebral hæmorrhage. In seventeen cases of idiopathic meningeal hæmorrhage which have come under our own observation, it was specially noted that there was comparatively little absence of cutaneous and muscular sensibility; that there was more or less rigid extension of the lower limbs, that the upper were often in co-ordinate movement; that there were tonic convulsive seizures of groups of voluntary muscles sometimes acting laterally, at others bilaterally; and what was of the most profound physiological interest, was not so much the presence of reflex and automatic movement, but the doubt which existed as to how far these movements were automatic, or in a measure voluntary. The psychology of meningeal hæmorrhage is of the greatest moment.

Dr. Hammond does not give us any new information concerning the diagnosis of plugging of the cerebral sinuses. In several of our own cases, we are bound to admit we found no essential diagnostic sign. In two, where the circulation was completely obstructed by growths of the torcular Herophili during life, nothing could be noted except vertigo, blowing noises in the ears, aberrant vision, and ischæmia papillaris.

In several cases where cerebral venous thrombosis was diagnosed, we have found large and frequent doses of liquor ammoniæ to be of essential service.

Concerning the very excellent article on cerebral softening, Dr. Hammond holds different views from Dr. Hughlings Jackson. The former looks upon it as a distinct pathological condition, which may exist independent of the vascular supply.

The various views upon the vexed and inexplicable question of aphasia, from an early date, are fully entered into, and especially the localisation of the faculty of language. Dr. Hammond does not believe in the doctrines of Broca's school, neither does he admit that the organ of language is restricted to the left hemisphere, for he says it is situated in both hemispheres, and in that part which is nourished by the middle cerebral arteries. It is clear that he draws his conclusions strangely enough rather from statistics [which in our opinion often furnish doubtful data] than from his own experience.

As in paralysis existing on the same side as the brain-lesion, so in aphasia, very rarely indeed do we find the right hemisphere to be the seat of lesion.

We do not think that any true physiological construction can be put upon traumatic injuries to the encephalon, unless the *post mortem* examination be conducted with the greatest care, and the microscope be brought into requisition.

It has not been our good fortune to meet with more than one case of aphasia, with well-marked left hemiplegia, out of 127; and in this case it was found upon examination that in addition to the remains of an old clot in the right corpus striatum there was

softening of the second and third frontal convolutions of the *left* hemisphere. Broca's theory is in a great measure supported by the physiological researches of Dr. Ferrier. Dr. Jackson's views tend to support this doctrine. Certainly our own pathological and clinical experience leads us to the most definite views upon this point.

Dr. Jackson's definition of the term aphasia ought to be generally adopted as indicating merely the want of voluntary power of using words to express ideas where mind (memory, perception, and receptivity) are not involved. If such definition, however, were adopted, it would reduce those cases which now come under the term aphasia to a minimum. All who have had clinical experience of this class of perverted function must have learnt that, whenever the speech-centre is involved, the balance of mind has at some time or other been disturbed. It matters not whether, according to Ferrier, the centre for co-ordinate articulate movements of speech act bilaterally, and exist in each hemisphere. The degree of mental derangement undoubtedly depends upon the precise location of the lesion and brain-involvement—let that be by inhibition through commissural fibres, or by defective vascular supply. It is interesting to find that, the more the study of brain-function advances, so much the more is it proved that the integrity of the brain as a whole is dependent in direct ratio not only with the parts immediately diseased, but indirectly by contiguity with anatomical relationship. We are more and more convinced that aphasia in the general acceptance of the term is not explained by mere ataxy of muscles of articulation.

Dr. Hammond states that he has purposely omitted giving an account of epidemic cerebro-spinal meningitis. We think this an unfortunate omission. And it would have been well if he had expressed his views concerning a disease which is becoming more frequent in this country, namely basic idiopathic cerebro-spinal meningitis of an acute nature. We have brought several such cases before the notice of the profession, but the precise etiology of this condition is obscure.

We think Dr. Hammond lays too little stress upon blood-states in reference to both acute and chronic disease of membranes of the brain and spinal cord; and the cases quoted by him appear to have their origin manifestly apparent in the gouty, syphilitic, rheumatic, or tubercular diathesis. We speak from clinical evidence, and consider them to arise from a subacute inflammation (if the term may be used) by a metastasis from the skin, joints, or connective tissue. It must not be forgotten that dissipation, alcoholism, deprivation of the necessities of life, and exposure to vicissitudes of temperature, are frequently exciting causes.

The more common forms of insanity are vividly portrayed. The description of the varieties of paralysis due to pathological changes in the several columns and grey matter of the spinal cord is a more complete one than we obtain in any other work in the English language, and the symptomatology, significance, physiology, and pathology of these cases appear to us to be far more explicit and interesting than any other part of the volume. The views of Charcot and Vulpian are expressed in direct conformity with their most recent and important investigations.

Dr. Hammond believes with Muller, Barth, and Lockhart Clarke that in pseudo-hypertrophic paralysis the lesion begins in the spinal cord, and that the

muscular change is secondary. In two cases which have come under our observation, no lesion was found in the spinal cord, thus bearing out the views of Charcot that the muscular lesion is the essential one. It is as yet an open question, which cannot be decided without further investigation.

In reference to progressive labio-glosso-laryngeal or bulbar paralysis, Dr. Hammond's views are extremely definite, so much so, in fact, that few observers can claim an equal share of precise information. We know that the medulla may be invaded by an interstitial inflammatory change, either from the cord or from the brain; and under these circumstances it does not, according to Dr. Hammond, come under the term. Nevertheless, such cases present all the characteristic features bilaterally of this disease.

Its invasion first affects the due pronunciation of lingual articulatory processes, then the labials; difficulty of swallowing and profuse secretion of the salivary glands follow. This, from our point of view, is a bulbar progressive paralysis, and in our experience those cases are rare where the anatomical lesion clearly shows that the motor (not trophic) roots of the seventh, eighth, and ninth nerves are alone involved. We will not attempt to disprove the existence of an entity which has been so clearly defined by Trousseau, Duchenne, Wachsmuth, and other learned observers, but from a clinical point of view we cannot accept a subjective theory in the place of objective phenomena; and what Dr. Hammond states to be mere weakness of the extremities, from the patient not being able to take sufficient food, we believe to be an actual invasion of the antero-lateral columns by inflammatory products. We quite agree with Dr. Hammond that some of the cases quoted from other authors by him are as far removed from true bulbar paralysis in signs and symptoms as a palsy from disease of the anterior columns of the cord is from loco-motor ataxia. Very little is said about the treatment of this affection, but upon this point we must be dogmatic. We know that the onward progress of the malady is certainly checked by paying strict attention (before the disease has advanced to that stage where lingual movements are stopped, and swallowing is performed with difficulty) to keeping the tongue, lips, and pharyngeal muscles at perfect rest, and to feeding the patient regularly through the nostrils. In one case which came under our care, by carefully pursuing this mode of procedure, the patient gained over two stone in weight, and for years followed his occupation until we lost sight of him.

Progressive locomotor ataxia is fully considered, and its anatomical seat is referred to the posterior root zones of the spinal cord. Dr. Hammond takes an isolated case as proof of this, and in one or two others it has been found that, where the columns of Goll have alone been diseased, the signs of locomotor ataxia have been absent. For our own part, we are willing to accept what we have found to be pathologically true, that the posterior columns, including the posterior root zones are principally and generally involved, but in advanced stages the inflammatory change has extended to the anterior horns of grey matter, and even to the anterior columns. Space will not permit us to comment upon Dr. Hammond's notice of muscular sense and the seat of co-ordinating power, which he gives in this chapter.

We find at page 772 an article on multiple cerebral

sclerosis. It seems to be thrown in between hysteria, epilepsy, and paralysis agitans, where it is out of place. There is a fairly interesting and true account of this most definite disease. We are indebted to Dr. Moxon, in 'Guy's Hospital Reports for 1875,' for the first published description of it in this country. Such a condition though has been known for years—in fact, according to our author, it was recognised thirty-five years ago by Cruveilhier and Carswell. From our own experience, we should say that there is no disease of the nervous system which denotes by clinical evidence its pathological significance with so much truth as this. The nystagmus, staccato speech, and jactatory motion of the head, with tremor and ataxy of movement somewhat as in sclerosis of the posterior columns, all tend to give to it a definite place in nerve nomenclature.

We can scarcely understand Dr. Hammond's reasons for differing from Charcot and other writers concerning the clinical signs of paralysis agitans; and we are disposed to think that here he is wrong. He states indirectly that the disease occurs in younger people, is somewhat curable, and not dependent on organic change. We have now under our care cases of paralysis agitans, cerebral sclerosis, and multiple cerebro-spinal sclerosis; the first is a disease of advanced life, the second of middle age, and the third usually occurs between twenty-five and forty. Dr. Buzzard, at the Clinical Society last year, brought forward two cases—the one of multiple cerebro-spinal sclerosis, and another of paralysis agitans, and drew a graphic contrast between the clinical features of the two conditions which were well known, and ought never to be confounded. Dr. Hammond says that paralysis agitans rarely terminates fatally. What he means by this we are at a loss to understand, as we never knew a case to recover. In one of our cases, where death occurred, the tremor finally ceased because the body and limbs were drawn forward in a state of perfect rigidity, so that the patient was moved about like a solid block. The microscopic examination of the brain and cord was made by Mr. W. H. Kesteven, and we give it in detail. At the commencement of the decussation of the anterior pyramids, the following appearances were noted. The nerve-cells were atrophied, undergoing granular pigmentary degeneration, and that form of degeneration called fuscous, in which the nucleus and nucleolus take the carmine staining brilliantly, but the rest of the cells remain of a granular yellow appearance. There was cortical sclerosis of the posterior and right lateral columns. There were also specimens of miliary and colloid degeneration. As we ascended in the examination of the medulla, the nerve-cells of the olivary bodies were found to be atrophied. The fibres of the auditory nerves were almost destroyed by miliary degeneration, which, with colloid change, had invaded the lower portion of the nucleus of the fifth nerve and the fibrous matter surrounding the olivary bodies. The cerebellum and brain all gave evidence of what Dr. Kesteven at one time designated miliary sclerosis, but in reference to which he now uses the more appropriate term 'miliary degeneration.' The appearances presented by the spinal cord were similar to those described in the medulla and brain. The cells in the anterior horns were particularly the seats of the various forms of fuscous degenerations.

Dr. Hammond tells us all that is known in relation to hydrophobia, and he seems to be doubtful whether it is a blood or nerve disease; and he gives the

same opinion in reference to tetanus. We consider both conditions to be due to blood-change. He recommends the use of nitrate of silver or cauterisation to the bitten surface. Our practice is to apply freely the strongest solution of ammonia.

The question of epilepsy is well studied and elaborated, and we are glad to find that Dr. Hammond endorses the sound psycho-physiological views of our distinguished neurologist, Dr. Hughlings Jackson as to what is and what is not epilepsy. The doctrine which was usually taught, that epilepsy, to be epilepsy, must be attended with unconsciousness, ought to be discarded. Yet Dr. Jackson's broad statements require much consideration, for, if we agree with him absolutely, all aborted functions are epileptic. We have long held the same views as Dr. Hammond relative to the blood-supply to the brain during epilepsy, and agree that a congestive form is equally as common as that induced by anæmia.

The chapters on chorea, athetosis, hysteria, ecstasy, and hystero-epilepsy are well worth perusal, and the book concludes with some practical remarks on toxic diseases of the nervous system.

There can be no doubt that this valuable work ought to be studied by every practitioner of medicine.

THOMAS S. DOWSE, M.D.

A Manual of Operative Surgery on the Dead Body. By THOMAS SMITH, Surgeon and Lecturer on Anatomy at St. Bartholomew's Hospital. A new edition, re-edited by W. J. WALSHAM, Demonstrator of Anatomy and Operative Surgery at St. Bartholomew's Hospital. London: Longmans and Co. 1876.

English surgery when compared with others, more particularly with French, is not rich in manuals of this kind. The first edition of this book was one of the best we possess, on account of the clearness with which it was written and the correctness of its details, as far as they went. The second edition, the preparation of which has been chiefly undertaken by Mr. Walsham, has not only been well revised, but has also been made more valuable by more frequent references to anatomy.

It has always appeared to us that, as the performance of many operations on the dead body is of but little use (compare, for instance, tracheotomy on the adult corpse with the same operation on the living child), the chief value of a course of operative surgery on the dead body (and equally so of a manual on the subject) lies in the opportunities which it gives to students of getting a good knowledge of surgical anatomy, and also of learning a number of those little practical points and helpful aids which can never be learnt so well as now, and which are too often left unlearned till the call comes to operate on the living subject.

We have already alluded to the attention Mr. Walsham has paid in this edition to anatomical details. Thus, in the chapter on ligature of the arteries, some useful diagrams on the collateral circulation, and on the relation of some of the chief veins to the arteries, will be found. On this account, especially in addition to its general excellence, this manual will be found useful by those preparing for the second examination for the Fellowship of the Royal College of Surgeons, under the new regulations.

It only remains to us to point out a few passages

which appear to us either quite needless or actual blemishes.

In the chapter on tenotomy, the directions for dividing the tendo Achillis from the dorsal surface forwards might well have been omitted; and the same might be said with regard to the paragraph on division of the tibial tendons at their insertions into the tarsus, such a step being one of great difficulty in a child, and often dangerous in an adult.

In the chapter on the genito-urinary organs, the following most unpractical directions are given for securing the cannula after puncturing the bladder by the rectum. 'It should be secured by fastening the end of the cannula to the margin of the anus . . . by means of sutures, or by tying it to the hair around this part' (p. 96).

Farther on, where amputation at the wrist-joint is described, it is much to be regretted that the editors should have contented themselves by transferring to their pages the most unintelligible account which is to be found in the manual by Mr. J. Bell, where, in amputating at the wrist-joint, it is recommended to begin at the junction of the outer and middle thirds of the arm (*sic*). Fortunately, the accompanying illustrations will enable the reader to puzzle out the steps of the real operation.

With all due deference to the opinions of the editors, we would recommend the student not to be satisfied with the three lines with which amputation at the elbow-joint is dismissed.

There are a few other passages which we had marked for comment, if our space had admitted it. On the whole, this book may be thoroughly relied upon both by the student in operating upon the dead, and the practitioner upon the living body.

RECENT FRENCH BOOKS.

Published by Adrien Delahaye.

- Expériences sur la force élastique des bandes et des tubes en caoutchouc par la méthode des poids, par M. le docteur Houzé de l'Aulnoit, professeur à l'École de médecine, chirurgien de l'hôpital Sainte-Croix. Lille, 1875, in-8 de 41 pages. Prix : 1 fr. 50.
- Discussion sur l'albuminurie et son traitement hydriatique, par Boulomié. 1 vol. in-8 de 48 pages. Prix : 1 fr. 25.
- Du choix d'une station thermale, par le docteur A. Comandré, médecin consultant aux eaux de Cauterets.
- Essai sur l'esthiomène de la région vulvo-anales, par le docteur Albert Faquet. Prix : 2 fr.
- Essai sur les contractures du col de la vessie, par le docteur C. Sebeaux. Prix : 2 fr.
- Goutte et rhumatisme, par le docteur Patezon, médecin inspecteur des eaux de Vittel. Prix : 1 fr.
- Les causes de la gravelle et de la pierre, étudiées à Contrexéville pendant neuf années de pratique médicale, par le docteur Debout, médecin inspecteur des eaux de Contrexéville. Prix : 3 fr.
- De la trépanation dans les abcès des os et dans l'ostéite à forme névralgique, par le docteur Simon Perret, ancien interne des hôpitaux de Lyon. In-8 de 88 pages. Prix : 2 fr.
- Du traitement chirurgical des hémorroïdes et en particulier de la dilatation, par Jean-Valère Cristofari. Paris, 1876.
- Traité de l'impuissance et de la stérilité chez l'homme et chez la femme, comprenant l'exposition des moyens recommandés pour y remédier, par le docteur Félix Roubaud. Troisième édition. Paris, 1876, in-8 de 804 pages. Prix : 8 fr.
- Étude expérimentale et clinique sur le thorax des pleurétiques et sur la pleurotomie, par le docteur J.-J. Peyrot, aide-d'anatomie à la Faculté de médecine de Paris. Paris, 1876, in-8 de 153 pages. Prix : 3 fr.
- Procédés pratiques pour l'analyse des urines, des dépôts et des calculs urinaires, par E. Delefosse, docteur en médecine. Paris, 1876, in 8 de 74 pages avec 68 figures. Prix : 2 fr. 50.

Contributions à l'étude des convulsions et paralysies liées aux méningo-encéphalites fronto-pariétales, par Louis Landouzy, docteur en médecine de la Faculté de Paris. Paris, 1876, in-8 de 248 pages avec 6 figures. Prix : 5 fr.

Du mode d'action des eaux sulfureuses, par le docteur Sénac-Lagrange, ancien interne des hôpitaux de Paris, médecin consultant des eaux de Cauterets. In-8 de 98 pages. Prix : 2 fr. 50.

Contribution à l'étude des kystes hydatiques compriment la moelle épinière, par le docteur P.-E. Désiré Bellement. In-8 de 60 pages et 2 planches. Prix : 3 fr.

Traité des tumeurs du sein, par Léon Labbé, chirurgien de l'hôpital de la Pitié et Paul Coyne, lauréat des hôpitaux. Un volume in-8 de 560 pages avec 2 planches en couleur et 32 figures. Prix : 12 fr.

Étude sur la transmission des sons à travers les liquides endopleurétiques de différentes natures, par le docteur Bacelli (de Rome), suivie de quelques considérations sur les signes physiques de la pleurésie, par le docteur Noël Guéneau de Mussy, médecin de l'Hôtel-Dieu, membre de l'Académie de Médecine. Paris, 1876.

Recherches sur les causes de l'épilepsie et des convulsions épileptiformes, par le docteur Durand Hugon (de Coltines). Prix : 2 fr.

De la fluxion ou congestion pulmonaire simple chez les enfants, par le docteur Hirne. Prix : 2 fr.

Published by G. Masson.

Recherches de chimie médicale sur l'hématine, (étude médico-légale), par le docteur Paul Cazeneuve, in-8 de 78 pages avec 2 planches. Prix : 3 fr.

Du traitement des ulcérations chroniques, (syphilis, scrofule, etc.), et des plaies atoniques par le sulfure de carbone, par le docteur Paul Guillaumet, in-8 de 63 pages. Prix : 2 fr.

Leçons cliniques sur les maladies de la peau professées à l'hôpital Saint-Louis, par M. le docteur E. Guibout, médecin de l'hôpital Saint-Louis, 1 volume in-8 de 700 pages. Prix : 8 fr.

La vie et ses attributs dans leurs rapports avec la philosophie et la médecine, par M. E. Bouchut, médecin de l'hôpital des Enfants-Malades, professeur agrégé de la Faculté de médecine, 2e édition, revue et corrigée. 1 vol. in-18 Jésus de 450 pages. Prix : 4 fr. 50.

Published by P. Asselin.

De la bronchite pseudo-membraneuse chronique, par le docteur Lucas-Championnière. In-8 avec une planche. Prix : 2 fr. 50.

De la médication marine, ses indications, ses contre-indications, ses avantages dans le traitement de la glycosurie par le docteur Hédouin, membre titulaire de la Société d'hydrologie médicale de Paris. Vol. in-18. Prix : 3 fr. 50.

Published by H. Lauweryns.

Eléments de pathologie et de clinique chirurgicales; par le docteur L. Moignac, ancien interne du hôpitaux. Tome I. 1 vol. in-18 Jésus de 760 pages, avec 85 figures intercalées dans le texte. Prix de l'ouvrage : 16 fr.

Published by J.-B. Baillière and Sons.

Expériences sur la force élastique des bandes et des tubes en caoutchouc par la méthode des poids, par M. le docteur Houzé de l'Aulnoit. Lille, 1875. In-8 de 41 pages. Prix : 1 fr. 50.

Du Merveilleux : Des Miracles et des Pèlerinages au point de vue médical, par le docteur L. Grellety. In-8 de 96 pages. Prix : 2 fr. 50.

MISCELLANY.

TIME'S WHIRLIGIG.—About the year 1832 an obscure Italian medical student, living in a poor lodging in the Rue de la Harpe, Paris, occupied his spare time by translating the works of Voltaire, of J. J. Rousseau, and of the surgeon Veaupeau. These philosophical and medical studies have borne fruit, and the unknown student of thirty years ago has returned to the scene of his early labours as General Cialdini, Ambassador from the kingdom of Italy to the French Republic.

PROFESSOR BARDELEBEN has been appointed Rector Magnificus, and Professor Virchow Dean of the Medical Faculty, of the University of Berlin. Professor Thiersch has been appointed Rector Magnificus of the University of Leipzig.

THE CATHOLIC UNIVERSITIES seem to have been a failure in France. According to an official account published by Government, about a hundred pupils have been registered in law. The number of medical students is limited to a few dozen, and there are only eight in science. However, the Catholics are collecting funds with unabated spirit, and 3,000,000 francs are said to be in hand for opening a Law Academy at Marseilles.

CONTAGIOUS PUERPERAL FEVER.—In the American supplement to the *Obstetrical Journal of Great Britain and Ireland*, Dr. Wells relates a case where a physician travelled 250 miles to attend the funeral of a lady who had died from puerperal fever, and arrived after the body had been placed in the coffin. He remained thirty hours in the house, but did not touch the corpse. On returning home, he attended, three days afterwards, a lying-in case, who caught the puerperal fever and died.

THE RIBERI PRIZE.—The Turin Academy of Medicine proposes the following subject for the prize of 20,000 francs (800*l.*) founded by Riberi. The pathology of the female genital system. The principal conditions are the following. 1. Complete treatises and monographs are admitted to competition. 2. Works may be either in print or manuscript. They may be written in Latin, Italian, or French. 3. The printed works must have been published in the course of the years 1874, 1875, 1876, and must be in duplicate. 4. The works of the candidates must be addressed to the Royal Academy of Medicine of Turin, before December 31, 1876.

CAMBRIDGE UNIVERSITY.—During the Academical year 1875-6, which terminated in June last, the University has been more prosperous than in any previous year, judging from the numbers entered and the degrees conferred. The number of students matriculated was 699, as against 672 in the previous year. The number of degrees conferred was 823, as against 787. The number of degrees in each faculty—Divinity, Law, Physic, Music, and Arts—was as follows:—Doctors in Divinity, 4; Doctors of Law, 3; Doctors in Medicine, 5; Doctors of Music, 2; Masters of Arts, 282; Masters of Law, 14; Bachelor in Divinity, 1; Bachelors in Medicine, 6; Bachelors of Arts, 473; Bachelors of Law, 25; Bachelors in Music, 6; and two graduates from other Universities were incorporated. Of the Bachelors of Arts and Law, 246 graduated with honours. The increase in the University may be estimated by comparing the above figures with the number of matriculations and degrees ten years ago, which was as follows:—Matriculated, 540. Degrees conferred, 647—viz., D.D., 3; LL.D., 10; M.D., 1; M.A., 249; Masters of Law, 5; Master in Surgery, 1; Bachelors of Arts, 241; Bachelors in Divinity, 5; Bachelors of Law, 30; Bachelors of Medicine, 2. In this total of 647 are included six honorary degrees.

THE UNIVERSITY LIBRARIES IN GERMANY.—The *Illustrirter Kalender* publishes the following statistics of the contents of the university libraries in Germany. The library of the Berlin University contains 115,000 printed volumes and 40,000 charts. The University of Bonn contains 180,000 volumes, several hundred manuscripts, and a large collection of maps. The University of Breslau has 340,000 volumes of books and 2,900 manuscripts. The Erlangen University has 110,000 printed volumes and 1,900 manuscripts, besides 50,000 treatises, 17,000 autograph letters, and a collection of designs and engravings. The Freiburg University contains 250,000 printed volumes and 500 manuscripts. The Giessen University has 150,000 printed volumes and 1,268 manuscripts; that of Göttingen, 400,000 printed volumes and 5,000 manuscripts; that of Greifswald, 70,000 volumes; and that of Halle, 100,000

volumes and 1,000 manuscripts. The University of Heidelberg has 300,000 volumes, 70,000 treatises, 3,000 manuscripts, 1,000 charts, a collection of maps, and another of engravings. The University of Jena has 100,000 volumes, and that of Kiel 150,000 volumes and several hundred manuscripts. The University of Königsberg has 220,000 volumes, in addition to about 50,000 double copies of books for the purpose of exchange. The University of Leipsic contains 350,000 printed volumes and 4,000 manuscripts. The University of Marburg has 120,000 printed volumes, but very few manuscripts. The University of Munich contains 283,500 volumes, 17,500 manuscripts, 3,600 portraits, and 3,200 medals. The University of Rostock has about 140,000 volumes; that of Tübingen, 280,000 volumes, 60,000 treatises, and 2,000 manuscripts; and that of Würzburg more than 200,000 volumes and 2,000 manuscripts. The library of the Strasburg University is said to contain 300,000 volumes, of which 5,400 relate to the history of Alsace, and about 500 manuscripts. The *Illustrirter Kalender* adds that the library of the Vienna University contains 211,220 volumes and 83 manuscripts, and that the library of the Basle University contains 100,000 printed volumes, 4,000 manuscripts, and 180 charts.

THE MEDICAL SCHOOL AT CONSTANTINOPLE.—This Medical School, placed under the direction of Dr. Bernhard, a German, and ten other able professors, all from Vienna, was at first established at Galata-Serai, an old Government Palace in Pera, but was rusticated to make room for the Lyceum, and removed to Kumbur-hané, near the Sweet Waters of Europe. The German instructors have now been superseded by ignorant native teachers, and the anatomical and other museums have suffered from frequent migrations. The surgeons and physicians required even for the naval and military services are still in a great measure supplied by foreign schools, and what ideas of the profession are entertained may be inferred from the fact that merely for lancing the Sultan's boil, an operation for which the meanest phlebotomist would be competent, Omer Pasha, the Court doctor, received a remuneration of 1,000*l.*, with some jewelry, and the rank of a General of Division. The continuous and conscientious habit of study and devotion to medical science does not recommend itself to the Turkish student, and the population is in the hands of quacks and wise-women sticking to the old superstitious practices of sorcery and ignorant empiricism.

THE SALE OF POISONS.—It would appear, from a lecture delivered before the Medical Society of London, by Dr. R. Farquharson, that the strength of several of the so-called 'mother tinctures' of the homœopaths is far in advance of that of the solutions sold by the allopathic chemists. It is well to notice this fact, as no restriction is placed on the sale of these dangerous preparations, so that they may be freely purchased with homicidal or suicidal intent. Thus, for instance, in the solution of arsenicum, of the first potency, arsenious acid was found to the extent of one grain in 102 minims of water; while the corresponding solution in the British Pharmacopœia contains only one grain of arsenious acid to 120 minims of water. Again, an analysis of the 'first potency' of mercurius gave one grain of bichloride of mercury (corrosive sublimate) in about two drachms of water, or four times the strength of the British Pharmacopœia solution of perchloride of mercury. The strength of the tinctures of aconite and belladonna was found also to be much greater than that of the recognised medical preparations. The analyses were performed by Mr. Brownen, the able analytical chemist of Messrs. Savory and Moore. Among the dangers to be anticipated by the unrestricted sale of such poisons as the above, besides the one already pointed out, the lecturer adverted to the 'rash confidence engendered in the minds of old-fashioned homœopaths regarding the weakness of the drugs, and the freedom with which they may be used. A mistake of this kind occurring with aconite would probably not happen to the same patient a second time.'

THE number of denizens of the Southport Aquarium has been lately increased by the birth of no less than 1,000 sea-horses in one of the tanks.

AN association to be known as the American Gynaecological Society was organised in New York on June 3. The officers for the first year are as follows: President, Fordyce Barker; vice-presidents, W. L. Atlee, W. H. Byford; secretary, J. R. Chadwick; treasurer, P. F. Munde; council, J. M. Sims, W. Goodell, T. Parvin, G. H. Lyman. The first meeting will be held in New York, on September 13, 1876.

IT is well-known that the population of France is increasing at the lowest rate in Europe, but that the rate is rapidly diminishing will be, perhaps, surprising to many. That, however, is the fact, as appears from some statistics which have been published by the *Economiste Française*. From the calculations of births over deaths it appears that taking periods of ten years since 1800, the rate of increase has been as follows: 1801-10, the population was doubling in 168 years; 1811-20, in 121 years; 1821-30, in 119 years; 1831-40, in 168 years; in 1841-50, in 168 years; 1851-60, in 228 years; 1861-70, in 265 years; 1871-75, in 1,380 years. The last number is of course unusually great, on account of the transfer of the Rhine Provinces to Germany. This gives 334 years for 1801-75, while Germany requires only 98 years to double its population; Austria, 62; Denmark, 73; the United Kingdom, 63; Sweden, 89; and Norway, 51.

UNIVERSITY OF LONDON: PRELIMINARY SCIENTIFIC (M.B.) EXAMINATION.—The following candidates passed the recent examination: *First Division*.—John Mitford Atkinson, London Hospital; James Balls, King's College; George Frederic Barnes, Melcombe Regis School; Frederic Thomas Bayes, Guy's Hospital; Edward Hargrave Booth, private tuition; Francis Bowe, St. Bartholomew's Hospital; George Coulson Robins Bull, Epsom College; William Fitton Chadwick, Owens College; William Chisholm, B.A. Sydney, University College; Ernest Clarke, St. Bartholomew's Hospital; Walter James Clarke, Queen's College, Birmingham; Daniel Colquhoun, Charing Cross Hospital; Augustus Henry Cook, University College; Robert Hammond Cotton, B.A., Owens College; Arthur Cutfield, Epsom College; Andrew William Dallmeyer, University College; Norman Dalton, King's College; Arthur George Dawson, Owens College; Edwin Deane, St. Thomas's Hospital; Henry Edmonds, private study; Joseph Faulkner, St. Bartholomew's Hospital; George Ernest Fooks, St. Bartholomew's Hospital; Joseph Tregelles Fox, London Hospital; William Fream, Royal College of Science, Dublin; Henry Thomas Groom, St. Bartholomew's Hospital; Robert Nightingale Hartley, private study; Henry Nelson Holberton, St. Thomas's Hospital; Richard Honeyburne, Liverpool Royal Infirmary School of Medicine; Robert Nesbit Hormazdji, St. Mary's Hospital; William Evans Hoyle, Owens College and Christ's Church, Oxford; David Alexander King, St. Bartholomew's Hospital; Thomas Kirsopp, St. Bartholomew's Hospital; Leopold Larmuth, Owens College; Charles Pardey Lukis, St. Bartholomew's Hospital; William Norton Macartney, Allesley Park College; Dennis M'Donnell, King's College; Robert Maguire, Owens College; Herbert Meyrick Nelson Milton, St. Thomas's Hospital; Arthur Newsholme, St. Thomas's Hospital; John Williams Nicholson, private tuition; James Norie, University College; Arthur Northcott, University College; Louis Coltman Parkes, University College; James Hugh Paul, private study; Arthur Edward Permewan, University College; Reginald Pratt, University College; Beaven Neave Rake, Guy's Hospital; Mark Feetham Sayer, University College; Thomas Ball Silcock, private study; Richard Sisley, St. George's Hospital; Robert Henry Scanes Spicer, private study; William Ainley Sykes, St. Bartholomew's Hospital; Frederick Rufenacht Walters, St. Thomas's

Hospital; Robert Blake Yardley, University College. *Second Division*.—William Coode Adams, University College; Theodore Frederick Pennington Adolphus, King's College; D. E. Anderson, University College; Anundrao Atmaram, University College; Gilbert Harry Barling, St. Bartholomew's Hospital; John Irvine Boswell, Guy's Hospital; James Lodwick Burchell, London Hospital; Dudley Wilmot Buxton, University College; Wayland Charles Chaffey, St. Bartholomew's Hospital; David Collingwood, Liverpool Royal Infirmary School of Medicine; John Davidson, King's College; Thomas Vincent Dickenson, St. George's Hospital and private study; John Arthur Diggle, Owens College and private study; Arthur William Dingley, University College; Denis William Donovan, University College; Howard Howse Dummere, St. George's Hospital; Edwin Hurry Fenwick, London Hospital; William Eckett Fielden, Guy's Hospital; William Henry Russell Forsbrook, Westminster Hospital; James Harper, University College and St. Bartholomew's Hospital; Walter Robert Thomas Hawkins, London Hospital; Edward James Hodges, private study; William More Hope, University College; Donald Templeton Hoskyn, University College; Thomas Isherwood, Owens College and private study; Edward Cocks Johnston, Queen's College, Birmingham; George Ryding Marsh, Guy's Hospital; Henry Maudsley, Giggleswick Grammar School; Robert Arthur Milligan, Guy's Hospital; Frederic Harvey Norvill, King's College; Edward Potts, Queen's College, Birmingham; James Havelock Alexander Rhodes, Liverpool Royal Infirmary School of Medicine; Henry Smith, St. Bartholomew's Hospital; Bernard Joseph Snell, B.A., New College; Julian Stephens, University College and private study; Thomas George Stonham, private study; Samuel Walter Sutton, St. Thomas's Hospital; Ernest Hamilton Wagstaff, King's College; Robert Spence Walton, University College; Christopher James Watkins, University College, and private study; Walter Wickham, St. Bartholomew's Hospital; Walter Treiving Williams, London Hospital; Louis Edmund Wood, St. Thomas Hospital.

The following passed the first B.Sc. Examination: *First Division*.—Arthur Black, private study; Thomas Bolton, University College; Ernest Henry Cook, Royal College of Science, Dublin; Robert Hammond Cotton, B.A., Owens College; Arthur Cutfield, Epsom College; Andrew William Dallmeyer, University College; William Fisher, B.A., private study; William Fream, Royal College of Science, Dublin; Thomas Gough, private study; William Henry Higgin, Owens College; Edward Hopkinson, Owens College; William Evans Hoyle, Owens College and Christ Church, Oxford; George William Mackie, B.A., private study; Henry Major, B.A., private study; Henry Forster Morley, B.A., University College; Michael Francis O'Reilly, St. Joseph's College, Clapham; John Arthur Owen, private study; James Hugh Paul, private study; John Marsden Raby, B.A., Owens College; Hermann Ludwig Theodor Sack, B.A., private study; Rajani Kanta Sen, Edinburgh University; George Severs, private study; John Shirley, private study; Thomas Ball Silcock, private study; George Thomas Smith, private study; Julian Stephens, University College and private study; Thomas Ebenezer Vasey, private study; William Leonard Wills, Owen College; James Thomas Wright, private study; Robert Blake Yardley, University College. *Second Division*.—Anundrao Atmaram, University College; Bolinarayan Borrah, University College; Walter Kenneth Griffin, University College; Edward James Hodges, private study; Thomas Isherwood, Owens College and private study; Miles Knowles, private study; Leopold Larmuth, Owens College; Walter Palmer, University College; James Runciman, private study; Bernard Joseph Snell, B.A., New College; John Trubert, St. Joseph's College, Clapham; Horace William Turner, University School, Hastings, and private study; Henry Ullyett, private study; James Beaumont Wohlmann, B.A., private study.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

CHARCOT AND GOMBAULT ON THE ALTERATIONS IN THE LIVER FOLLOWING LIGATION OF THE BILE-DUCT.

MM. Charcot and Gombault (*Archives de Physiologie*, May and June, 1876), have endeavoured to work out more completely the details of this process, to which already much has been contributed by the researches and writings of Cornil, Leyden, Mayer, and Wickham Legg. The animals selected for observation were guinea-pigs, and the observations were seven in number. Five animals died between the fifth and twelfth days after the operation, the sixth was killed on the tenth day and the seventh on the twenty-third day. The course of the bile to the intestine was in no case re-established; the consecutive peritonitis was limited, and the general peritoneal surface presented neither redness nor false membranes. The animals during life showed no special symptoms; they rapidly became thin, lost their appetites and died; they never were icteric; and the urine never gave the reaction of bile with the nitric acid test. The liver in every case was considerably enlarged; its colour was pale yellowish, and nutmeg-like, the centre of the lobule being yellow and translucent, the periphery slightly red: its consistence was increased, hard and resistant; there was no appearance of granulations.

The bile-apparatus outside the liver was dilated, its walls thickened and opaque. On microscopic examination, its connective tissue was found infiltrated with leucocytes. At the hilus, the connective tissue was in a similar condition; the usual adipose cells had disappeared. The bile in the gall-bladder was thick, and mixed with much mucus and masses of epithelium. In one case, where the bile was examined immediately after the animal was killed, by section of the medulla, it was found to contain a number of moving vibriones. In the liver itself, the large bile-ducts were greatly dilated, exceeding the diameter of the accompanying vein, and lined by large cylindrical epithelium; their cavities were generally free except in the case of the smallest, which were sometimes blocked by solid concretions of bile-pigment. Their walls were confounded with the connective tissue of the portal canals, which had become embryonic, without being much increased in quantity. The accessory bile-ducts were also enlarged; and this increase was due both to dilatation of their lumina and augmentation in the height of their epithelium.

The changes in the blood-vessels, which seemed of secondary importance, varied very much, the vein being sometimes dilated and filled with clot in which leucocytes were very numerous; at other times the epithelioid lining was evidently proliferating, but the

other coats were normal. There was nothing to notice in the arteries and lymphatics. The interlobular fissures and spaces presented changes varying according to the stage of advancement. At first, under a low power, the area of the spaces was simply enlarged, and their angles were prolonged more than usually towards the fissures; later, the fissures themselves had disappeared, and were replaced by bands of newly formed tissue, causing the lobular structure to be well marked, each lobule being surrounded on all sides and separated from its neighbours. Still later, the newly formed tissue had extended at the expense of the glandular substance, until it almost reached the central veins of the lobules. With higher powers, the canaliculi of the spaces were found dilated, often empty, sometimes containing a little biliary calculus, and presenting on their walls a lining epithelium like that of the larger ducts. As the spaces and fissures became larger so the number of the canaliculi increased until they presented the appearance of a network with irregular meshes, and capable of being distinguished as forming three zones, one of which was usually absent in the fissures. Those in the central zone were large, and few, occupying the neighbourhood of the vein, and usually absent in the fissures; in a second zone of more numerous but smaller canaliculi than the preceding, the canaliculi ran at right angles to the rows of hepatic cells; and, lastly, there was a third zone of very short canaliculi branching off at right angles from the last and running parallel to the direction of the rows of hepatic cells, with which, in some places, they seemed to be continuous. The contents of these canals varied; sometimes they were completely filled with epithelium; sometimes the epithelium formed an irregular investment of the inner surface, and then all the intermediaries between the small cubic epithelium of the fine interlobular canaliculi and the cylindrical epithelium of the larger canals could be observed; sometimes the canaliculi contained bile-pigment. The development of the interlobular connective tissue seemed to follow step by step the development of the canaliculi; embryonic and infiltrated with lymphatic elements when the lesion was but little advanced, it progressed towards complete organisation as this proceeded. The hepatic lobules underwent at first only a modification of size proportional to the enlargement of the spaces, except that the radiating vessels contained only white corpuscles, the red blood-corpuscles being entirely absent. As the lesion advanced, the lobule underwent important changes, not by compression, but by absorption of the hepatic cells, the new formation following the rows of cells. The precise manner in which the hepatic cells disappeared was not perfectly determined. The protoplasm seemed to diminish in quantity without any apparent change in its character—a sort of simple atrophy; fatty degeneration was only observed exceptionally. Occasionally, either in the neighbourhood of one of the microscopic abscesses, which were scattered through the liver or in the neighbourhood of small, dense, yellow patches, which seemed caused by the plugging of a canaliculus and the exudation of bile, a sort of vitreous degeneration of the cells was observed, the protoplasm of the cell becoming clear, homogeneous, slightly yellow, and resisting the action of all colouring agents.

The authors dissent from the the conclusion of Dr. Wickham Legg, that the phenomena are due to

a propagation of traumatic irritation from the part ligatured along the ducts, because this view ignores the influence of the retention of bile, and because, in one of Dr. Legg's cases, the left branch being alone tied, the traumatic irritation should have propagated itself in all directions, and should have affected the right lobe as much as the left, but the necropsy revealed lesions of the left lobe only; and, lastly, because in two other observations of the same author after ligature, the course of the bile was re-established, and in these ligature alone was shown to be powerless to determine the cirrhosis. The retention of bile, according to the authors, causes, first, and most manifestly, dilatation of the canals; and, secondly, proliferation of their epithelioid lining; this last is due probably, not to the simple chemical influence of the bile, but to properties acquired by it in the changes which it undergoes during its stay in the dilated receptacles, *dépropos* of which they refer to their observation of the presence of vibrones in one case. The increase in the number of the canaliculi is believed by them to be due to a transformation of the intralobular canaliculi, because they tend to substitute themselves for the rows of hepatic cells, and thus occupy the positions of those biliary capillaries described by Eberth and by Hering. Sometimes the transition from hepatic cell-row to biliary duct is very gradual, the normal hepatic cell diminishing gradually in volume, then flattening itself while it retains a certain quantity of its granular protoplasm, to be finally replaced by a little cell identical in appearance with the epithelium of the canaliculi. Moreover, in other places the intralobular canaliculi dilate and anastomose with the canaliculi of the spaces; the circumference of the lobule appears riddled with lacunæ which, on the side of the interlobular space, are limited by little cells, with large nuclei like those found in the neighbouring bile-ducts, while those which approach the lobule are surrounded by true hepatic cells, only these cells are flattened and their protoplasm tends to disappear. It is possible to follow a longitudinal section of a true biliary canaliculus, and to observe directly the continuity of its cavity with such a lacuna.

As to the origin of the epithelium of the newly formed canaliculi, the authors advance two hypotheses. Either it is formed by extension of the irritative process which led to epithelial proliferation in the larger ducts, or it is formed from the hepatic cells themselves, but they consider on this point further observations are required. Ligature of the bile duct is not the only experimental procedure which can determine cirrhosis of the liver, for in 1872 M. Solowief showed that ligature of the vena portæ produces an analogous result. The authors hope to show in a future paper that there are, anatomically, three easily recognisable types of cirrhosis of the liver: 1. Multilobular cirrhosis, common granular liver, in which rings of fibrous tissue surround and compress the lobules; 2. Unilobular cirrhosis, or hypertrophic cirrhosis, in which the connective tissue does not compress, but systematically destroy, the hepatic cells following the direction of their rows, and proceeding from the circumference to the centre; 3. Pericellular sclerosis, affecting primarily the intralobular connective tissue, as in the syphilitic hepatitis of new-born children. The notes of a case of partial obstruction of the common bile-duct by a gall-stone, with the microscopic appearances of the liver presenting analogous changes to those above described, and a reference to a case published by Dr. Bea'e,

are advanced to show that this pathological condition does occur in the human subject.

ROBERT SAUNDBY, M.B.

MORSELLI ON THE PATHOLOGY OF THE CERVICAL SYMPATHETIC NERVE.

Dr. Morselli, of Florence, commences an article in *Lo Sperimentale* for August, by remarking that up to the present time the study of affections of the great sympathetic has been attended with considerable difficulty, in comparison with that of other nervous diseases. In the first place, our knowledge of the trophic and vaso-motor functions of the sympathetic is as yet incomplete. Secondly, while we possess numerous facts regarding the anatomical and microscopical lesions of the sympathetic system, especially through the labours of Foà, De Giovanni, Eulenburg and Guttmann, Lubimoff, Ebstein, etc.,* we have made but little advance in determining the relation between the various forms of lesion and certain groups of symptoms. Facts showing the relation between morbid symptoms and changes in the sympathetic are very rare; up to the present time, science has registered in this respect only one characteristic group of phenomena, that dependent on lesions of the cervical sympathetic. These facts, which are already sufficiently numerous, have confirmed in man the functional laws which physiopathology had discovered in animals.

CASE. *Cerebral Tumour (Gliosarcoma); Paralysis of the Right Cervical Sympathetic and Irritation of the Left; Fatty Degeneration and Atrophy of the Ganglion-cells.*—Marianna Carrani, aged fifty-five, was admitted into hospital on February 13, 1876. Up to the age of forty-five she had enjoyed excellent health. She had had two normal labours; and there was no history of nervous disease in her family. At the age of forty-five she began to feel weak in her legs, stumbled readily, and had intercurrent headache. Her strength diminished rapidly, especially in the lower limbs; these in a short time became affected with paresis, which passed into paralysis in the right leg. She was treated by her medical attendant for an affection of the spinal cord, by baths and by internal remedies of which the nature could not be ascertained. She became subject to frequent attacks of vertigo and intense headaches, which confined her to bed while they lasted; otherwise she continued to attend to her household duties, so far as the progressive loss of strength and the paralysis would allow.

Towards the end of December, 1875, she grew worse. The attacks of headache, limited especially to the right side of the cranium and to the forehead, became more frequent and more severe; she occasionally had vomiting, and the attacks of vertigo occurred several times in the course of a day. But there was no emaciation in proportion to the severity of the symptoms; the patient retained her robust and florid appearance. On February 12, the attacks

* Foà, Pio, 'Sull' anatomia patologica del gran simpatico. (*Rivista Clinica di Bologna*, 1874. De Giovanni, A., *Rendiconto dell' Istituto Lombardo*, Milano, Serie II., 1874. Eulenburg and Guttmann, 'Die Pathologie des Sympathicus auf physiologischer Grundlage,' Berlin, 1873. Lubimoff, 'Beiträge zur Histologie und patholog. Anatomie des sympathischen Nerven System,' *Archiv für Pathol. Anat. und Physiol.*, vol. xi., 1874. Lubimoff, *Archives de Physiologie Normale et Pathologique*, 1874.

of vertigo were so severe as to oblige her to go to bed. During the night she fell into a comatose state, and her family, believing that she had cerebral apoplexy, sent her into the hospital. When Dr. Morselli saw her on the evening of the 13th, the following was her condition.

She was a woman of robust formation, with an abundance of fat. She was bull-necked. She lay on her back in a state of complete muscular relaxation, in profound coma, with laboured respiration. The pulse was 80, the temperature 38.5° Cent. (102.3° Fahr.). The face was turgid, the eyes were closed, and there was abundant lacrymation from the right. The redness of the face was less intense on the left cheek than on the right; the conjunctivæ were not injected. The pupils were equally dilated, and reacted very slightly to stimulants. The reflex movements of the eyelids were preserved. There was complete relaxation of both the upper and lower limbs; sensation was abolished, but the reflex movements produced by tickling, etc., were exaggerated. The patient did not answer questions, and passed her urine and feces involuntarily. Dr. Morselli ordered a leech to be applied to each mastoid region, and large sinapisms to the legs, with cordials and tonics internally.

Towards the next morning, she regained a certain amount of intelligence and sensation, and was able to understand and answer questions. In two hours, however, she relapsed into a state of coma. An examination at the morning visit by Professor Paganucci and Dr. Morselli ascertained her condition to be as follows. Intelligence, sensation, and voluntary motion were quite lost; reflex movements were performed, though feebly, in the lower limbs, but were lost in the eyelids. The left upper limb and both lower limbs were in a state of muscular relaxation; there was contraction almost amounting to rigidity in the right upper limb, which was semiflexed. The pulse was 78, strong, irregular, and full; the respirations 24, deep, almost stertorous. The right half of the face was intensely red; the left, on the other hand, appeared very pale in comparison. The redness on the right side was spread over the forehead, cheek, nose, lip, chin, ear, and neck, and even partly over the shoulder. A distinct straight line passing downwards from the forehead to the neck separated the red from the pale region, but the limit was not so distinctly marked on the back of the neck and shoulders. On careful observation of the reddened half of the face, there was seen to be a fine injection of the cutaneous capillary network; the vessels appeared turgid, and, as it were, enlarged. This vascular turgor was especially apparent in the zygomatic region and cheek; and the contrast between the two sides of the forehead was very remarkable. The patient's face was completely like a domino mask, having one side red and the other white.

The right half of the face was turgid and more voluminous than the left. The difference was especially marked in the ears, the right presenting a most intense odoration, manifest turgor, and rosy transparency.

The skin of the right half of the face was moistened with sweat, while the left was quite dry. The sweat was collected in small drops, confined to the right side of the face and neck. The temperature on the right side was higher than on the left; the right ear actually felt warmer than the left. Unfortunately, no thermometric examination was made.

The right palpebra was more congested than the left, and there was greater vascularity of the right conjunctiva. The right pupil was more contracted than the left, although the contraction of both was very great. The left pupil was normally sensitive to light; the right was almost insensible to ordinary light, but was very slightly affected by the light of a candle. The right eyeball appeared on pressure and palpation to be slightly more flaccid than the left. No difference as regarded pulsation, volume, or resistance, could be detected between the carotids on the two sides. The result of physical examination of the organs of the chest and abdomen was absolutely negative.

In making a diagnosis, the idea of disease of the spinal cord was at once set aside, as being incapable of accounting for the headache, the vomiting, and the general course of the patient's illness. The symptoms pointed especially to lesion of the anterior lobes of the brain, and of the large ganglia at the base. But what was the nature of this lesion? It had been supposed to be cerebral hæmorrhage; but the patient's present condition, which gave rise to this supposition, had been preceded by symptoms of a slow affection of the nervous centres, indicated by paralysis, headache, debility, vomiting, and vertigo. It could not be doubted that there was a connection between the two. The case was evidently one in which a slow disease of the brain had arrived at its last and fatal stage. In favour of the probability of a tumour were the recurrent attacks of intense headache, the length of the illness, the vomiting, the long standing paresis of the right leg, and the contraction of the upper limb of the same side. It might, indeed, be supposed that the tumour was at first limited to a part of the brain in relation with the motor functions of the paralysed limb, while the contraction could be explained as a result of irritation, propagated to a neighbouring part. It was thought probable that there was a tumour, the progress of which had been slow, developed in the anterior part of the left hemisphere, and specially affecting the corpus striatum.

But there are other points of special interest in the history of this case—those connected with the sympathetic nerve; viz.

1. *In the right half of the face and neck*; increased temperature, injection of the capillaries, excessive sweating, congestion of the conjunctiva, narrowing of the palpebral aperture, very marked myosis, flaccidity of the eyeball, turgor of the ear and face.

2. *In the left half of the face and neck*; lowered temperature (in comparison with the right side), pallidity, dryness of the skin, considerable mydriasis, and increased ocular tension.

The first idea which Dr. Morselli formed, and in which he was supported by Professor Paganucci, was that there was an affection of the sympathetic. The symptoms observed corresponded with those observed by Claude Bernard and others, as the result of injury and disease of the cervical sympathetic. No lesion of the organs of circulation or of the central nervous could explain the symptoms observed in this case. It is quite well known in chemical experience, that compression of the sympathetic by tumours, or wounds of this nerve, as well as certain unilateral affections of the cervical spinal cord and brachial plexus, are accompanied by certain symptoms in the region supplied by the cervical sympathetic, which presides over the vaso-motor and trophic functions of the corresponding half of the head, and,

by its anastomosis with the oculo-motor nerve, exercises a marked influence on the eye and the pupil. In many of the cases related by Ogle, Demme, A. Eulenburg, Roszbach, Porteau, Mitchell, etc., there were unilateral symptoms; sometimes, but rarely, these were cardiac symptoms, without doubt connected with the sympathetic. In a case recorded by P. Guttman (*Berliner Klinische Wochenschrift*, August, 1875) the principal symptoms were exophthalmus, dilatation of the pupil, sanguineous sweating, redness of the face and neck, lacrymation, increased heat—all on the left side; the cervical sympathetic was painful on pressure. The same occurred in the cases of Seguin, Ebstein, Eulenburg, etc. The identical phenomena observed in experiments on animals are indeed not repeated in every casual case; sometimes one is absent, sometimes another; sometimes the order of their occurrence is inverted, as occurred in Guttman's patient, in whom there occurred at the same time symptoms referable to paralysis (excessive sweating, redness, etc.) and others referable to irritation (mydriasis). In the present case, the symptoms on the right side pointed to paralysis or paresis, and those on the left to irritation, of the cervical sympathetic.

In the afternoon of February 14th, the left half of the face and neck became slightly reddened and in the evening both sides were uniformly red and sweating, and both pupils had become almost insensible to light. The patient died early in the morning of the 15th, the coma having been before death interrupted by convulsions.

At the necropsy, there was found to be a tumour on the anterior part of the left cerebral hemisphere, extending into the corpus striatum. The tumour, which was carefully examined by Dr. Brigid, was found to consist: 1. In some parts of stellate cells, having among them much soft and finely granular cellular substance; 2. In other parts, of fusiform cells or globules of embryonic tissue united by a very scanty basement-substance; the morbid tissue was traversed by numerous blood-vessels, especially in the part formed of fusiform cells. These characters indicated the tumour to be a specimen of gliosarcoma (Virchow). There was no indication of new growth in any other part of the body.

While the presence of this tumour accounted for the symptoms observed during life, there was some ground for doubting, from the result of the *post mortem* examination, whether it entirely explained the sudden attack which preceded death. There was old endarteritis in the aorta; fragments of old coagula were found to have entered the circulation, and there was fatty disease of the heart. The suddenness of the last symptom led to the suspicion that there might have been embolism of the cerebral arteries. Emboli were indeed found in the spleen and kidneys, but their presence in the brain was not ascertained, the examination not being extended to the ramifications of the vessels.

Examination of the sympathetic nerve gave the following results. The right inferior cervical ganglion was larger than the left, but both were larger than normal. They presented a pale grey colour, especially the right ganglion. The semilunar ganglion was distinctly atrophied, and much paler than those in the neck. The other parts of the sympathetic nerve presented nothing special.

The superior cervical ganglia were immersed in alcohol for two days, and were then cut into very

thin slices, which were coloured with carmine and preserved in glycerine. Examination of these gave the following results.

1. *Ganglion-Cells*.—These were rather scarce in all the preparations, and had undergone various changes. Those which approached nearest to the normal state had their protoplasm infiltrated with pigment-granules of a red or orange colour, to such an extent that the outline of the nucleus could not be distinguished, and the nucleus could only be made out through its refrangibility.

Other cells were much reduced in size, had entirely lost their normal structure, and appeared as shapeless bodies composed of masses of granules, mostly pigmentary. Around these cells was a large amount of connective tissue, which surrounded them in such a way as to deprive them of nutriment, thus accounting for their atrophy.

Other ganglion-cells, equally and sometimes still more atrophied, contained small fat-drops lying towards one side of the enveloping capsule. These fat-drops were probably produced by degeneration of the epithelioid lining of the capsules. In other cells, small drops of fat were scattered in the protoplasm.

In some parts of the preparations, enteric patches of ganglion-cells were found to have completely undergone fatty metamorphosis, being, in fact, transformed into true adipose vesicles. In some of these vesicles the fat was fluid, homogeneous, and very transparent; in others it appeared to be coagulated or crystallising.

2. *Nerve-fibres*.—Those containing myeline were very scarce; the so-called fibres of Remak were much more abundant, but were altered in structure, being reduced in size, as well as their nuclei. Where the ganglion-cells had undergone fatty change, many fat-drops were found lying free between the fibres, sometimes arranged in series, as has been described by Lubimoff.

3. *Interstitial Tissue*.—In some parts this was greatly increased, and presented the microscopic characters of fibrillar connective tissue after being acted on by acetic acid, all trace of fibre having disappeared, and the nuclei alone remaining. At some other points, as in the right cervical ganglion, there was found a small area exclusively formed of connective tissue, substituted for the ganglion-cells and nerve-fibres. On the other hand, where fat was abundant, the connective tissue was almost in normal proportions.

4. *Blood-vessels*.—The vessels of the ganglia were generally obliterated by thrombi, and in one of the largest a large drop of fat was found. All the vascular canals had thickened walls, of fibrous appearance, and the membrana adventitia was in a state of proliferation. The thrombosis of the vessels was beyond doubt of old date, perhaps anterior to the fatty degeneration of the ganglia.

All these changes were more marked in the right upper cervical ganglion; in the left the first stages of the disease, and in the right the ultimate stages, could be studied.

The cervical sympathetic in this case then presented the following conditions: 1. Pigmentation, atrophy, fatty degeneration, and destruction of the ganglion-cells; 2. Atrophy and degeneration of the epithelioid elements of the nerve-capsules; 3. A special degeneration of the fibres of Remak; 4. Proliferation of the interstitial connective tissue, and, later on, deposit of free fat in it; 5. Thrombosis of

the capillary vessels, multiplication of the nuclei in and thickening of their walls, and fatty degeneration of the contents of the vessels. All this may be summed up as sclerosis and fatty degeneration of the cervical sympathetic. Lubimoff, who has made the most extensive researches in the pathology of the ganglionic system, says that fatty degeneration of the cells of the sympathetic is rare: in 250 bodies, he found it only once, in a cancerous patient. Professor Foà, from his researches on the same subject, concludes that in most cases of pigmentary infiltration the pigment originates in the cell itself.

In its clinical aspect, this is one of the very few cases hitherto noted (if it be not the first in which the diagnosis of disease of the sympathetic during life has been confirmed by microscopic investigation. Dr. Morselli is acquainted with only two cases in which it has been possible to make an examination of the sympathetic believed to be affected. One of these is related by Seguin in the *American Journal of the Medical Sciences* for October, 1872. A man, aged fifty, had abdominal cancer. For a long time he had sweating of left side of the face, the right side being dry. At the necropsy, the right sympathetic was found adherent to the sheath of the vessels, and towards the bifurcation of the common carotid was much congested; the left sympathetic was normal. The only histological change noted was slight increase of pigmentation in the cells on both sides. The result of examination in this case, Dr. Morselli observes, is negative, since the pigmentation of the ganglion-cells varies in different individuals (Lubimoff). Ebstein describes in Virchow's *Archiv*, Band lxii., a case of unilateral sweating of the head, in which the cervical ganglia on both sides appeared of normal size and consistence. But, on hardening them in Müller's solution, one could see with the naked eye, in the ganglia corresponding to the affected side, points as large as a grain of sand, with round outline, and of a brown colour. These were formed of enormously dilated and varicose blood-vessels. There appears to be no report of a microscopic examination.

The alterations in the cervical ganglia explains the symptoms presented by the patient Carrani during the last days of her life. On the right side, where the pathological changes in the superior cervical ganglion were most advanced, the symptoms were more marked than on the left side, where the change appeared to be only in the first stage. On the right side, the paralysis produced by the morbid process was fully developed; on the left side, there was probably simple irritation of the sympathetic. The case presents other important questions for selection; for instance, how far the presence of the cerebral gliosarcoma may have disturbed the nutrition of the sympathetic to such an extent as to cause so grave an alteration in the cervical ganglia. Lubimoff, Foà, Poncaré, Petroff, and others who have studied the pathological anatomy of the sympathetic nerve, say that they generally found it oftenest in chronic diseases, especially cancerous and sarcomatous affections, tuberculosis, syphilis, and progressive paralysis. There might then be supposed to be some relation between the gliosarcoma and the disease of the sympathetic in the case of Carrani; but there was no formation of new growths in other parts of the body. Moreover, gliosarcoma of the brain belongs to the class of more benign sarcomata, which are developed slowly and very rarely tend to become generalised; hence it is not

probable that the tumour had much direct influence on the sympathetic. Another question for consideration is, whether the presence of the tumour may not have affected the vaso-motor nerve-fibres which pass in the brain to the surface of the cerebral lobes, and by irritating them, have interfered with the contractions of the superior cervical ganglia to such an extent as to cause their degeneration.

SCHWABACH ON THE PATHOLOGY OF THE CERVICAL SYMPATHETIC NERVES.

Dr. Schwabach, of Berlin, remarks (*Berliner Klinische Wochenschrift*, July 17, 1876), that, although neuroses in the domain of the sympathetic nerves can no longer be regarded as rare, yet their complexity is such as to justify the publication of those cases which occur from time to time. In one series of observations the phenomena are chiefly those of irritation, in another series the symptoms are chiefly paralytic, whilst a third set combines both in a well-marked manner. To this third kind we must refer the instances where the fibres supplying the pupil of the eye, and the eye itself, are irritated, whilst the vaso-motor fibres are paralysed. And again, there are cases in which there is an abnormal secretion of perspiration in some limited spot. The patients whose histories are subjoined sought advice for their deafness and ear affections, and did not complain much of the other symptoms, due to the sympathetic. The cases are as follows.

1. S. K., aged twenty-one, a sempstress, suffered from deafness in the left ear. The cause appeared to be a narrowing of the meatus auditorius externus due to an exostosis on the anterior wall. The passage was narrowed to a mere chink. The whole of the right side of the face, forehead, cheek, and region of the nose, as well as the right ear, showed a diffuse redness, and the temperature was perceptibly higher than on the other side, particularly in the ear itself. The patient said that this region was still hotter when she ate, or was excited, or on hot days, and that on such occasions there was a very abundant flow of perspiration on this side only. No pain was complained of. There was nothing abnormal on the left side. Both ocular apertures were alike; and no difference could be discovered in the size of the pupils.

2. W. P., a tailor, aged forty-three, had suffered from childhood with discharge from both ears. For many years past he had not heard at all in the left ear, and very badly with the right one. This patient's speech was somewhat indistinct. The membrana tympani on both sides was represented by a mere ring; the mucous membrane of the middle ear was pale red, and swollen. Nothing was to be seen of the ossicles on either side. The right side of the face showed redness on the forehead and cheek, extending from this to the right temple, and to the region of the right ear, which again was most intense in the external ear itself. The temperature in this case was perceptibly raised on the right side. There was no visible perspiration, but the patient said sweating occurred here on the least exertion. The right ocular aperture was less, and the right pupil manifestly smaller than the left side. Accommodation seemed unaffected. There was no discoverable cause for this affection of the sympathetic. There were no tumours, and no sign of any traumatic lesion in the neck.

3. E. A., aged twenty-three, a needlewoman, sought advice on November 29, for a slight attack of left-sided otitis externa. The walls of the meatus auditorius externus were reddened, slightly swollen, and the vessels of the membrana tympani in the course of the handle of the malleus and round the periphery were injected. The membrane itself was very slightly affected. The luminous cone (*Lichtkegel*) was wanting. (See Hinton's translation of Von Troeltsch's 'Diseases of the Ear' New Syd. Society, pp. 4 and 15.) The neighbourhood of the tragus was sensitive to pressure. A watch was heard at four inches. After inunction of blue ointment in front of the ear, and bathing with lukewarm water, the inflammation subsided, so that on December 3 the pain had vanished, and even the subjective feelings were nearly all relieved. On December 13 the patient returned, and complained of pain in the left side of the neck. A lymphatic gland, of the size of a hazel-nut, and tender on pressure, was found close to the angle of the lower jaw, and the subcutaneous areolar tissue round it was swollen. At the same time there was an intense redness of the whole of the left face, and the neighbourhood of the left ear—which was again most evident in the pinna. There was no swelling of the external ear or of the meatus, though the latter was slightly reddened. The ear-speculum and thermometer gave no pain. The temperature of the right meatus auditorius externus was 36° 6' C. (97° 8' F.) whilst that of the left was 37° C. (= 98° 6' F.) The conjunctiva of the left eye was reddened, and the secretion of tears increased. The ocular aperture and diameter of the pupil were alike on both sides. Neither patient nor doctor observed any abnormal perspiration. Before the redness set in, she had several times an intense feeling of cold and shivering on this side, which vanished every time after a few minutes. Mercurial inunction was again prescribed, and the glandular swelling subsided, so as to be imperceptible by December 20. But the redness of the left face was still perceptible, though less marked. The patient said that tears still flowed freely from the left eye. This, however, was not seen by the doctor. On December 28 all these symptoms had vanished. In all these cases the vaso-motor nerves were affected. In only one the oculo-pupillary. This is exceptional according to Guttman ('Zur Pathologie des Sympathicus,' *Berliner Klin. Wochenschrift*, 1875, no. 32.) In the *Archiv für Augen- und Ohrenheilkunde*, (1875, vol. iv. part 2,) Burnett details three cases of deafness and noises in the ears, with redness of the parts near the ear, and considers them examples, in all probability, of central irritation of the sympathetic nerves. In these cases oculo-pupillary symptoms appear to have been absent. Increased perspiration is less common than the redness. Increased lachrymation seems to be still more rare. In all the accessible literature Dr. Schwabach could only find five cases of this symptom. He refers to the authors mentioned in the foot note.* Dr. Schwabach considers that

* Weir Mitchell, Morehouse and William Keen, 'Gunshot Wounds and other Injuries of Nerves,' Philadelphia, 1864. Seeligmüller, *Berlin. Klin. Wochenschrift*, 1872, no. 4. only the last of the cases recorded above can be justly considered as dependent on the ear-affection, although all three were most probably to be referred to the sympathetic nerves.

W. BATHURST WOODMAN.

THE THERAPEUTICS OF HEADACHE. BY A. A. SMITH, M.D., LECTURER ADJUNCT UPON CLINICAL MEDICINE.*

We take up to-day the therapeutics of certain forms of headache, a very important subject. Headache may be divided into organic and functional; but I believe you will get a better idea of the treatment by dividing the cases according to the causes.

Neuralgic Headache.—A headache, when due to nervous disturbance, such as occurs in hysterical or excitable subjects, if associated with plethora, often yields to a saline cathartic. The most agreeable is the solution of citrate of magnesia, and should be given, a full bottle of it, on an empty stomach. In addition, it is well to give one of the bromides combined with valerian. The following prescription I frequently use:

R Sodii bromidi, ʒvj
Elix. valer. ammoniat. ʒiv.

M. Sig. ʒj. every hour until relieved.

If such nervous headache be associated with anæmia, after relieving the immediate attack with the bromide and valerian prescription, give iron, and give it for weeks, until there is a decided improvement in the patient's condition. Always give the iron after meals. In these anæmic cases it is often advisable to stimulate the heart's action. For this purpose I have found the following useful:

R Ammonizæ muriatis, ʒss.
Tincturæ actææ racemosæ,
Aquæ, aa ʒijj.

M. Sig. ʒij. after meals in a wineglass of water.

If there be despondency and depression of spirits, phosphorus, with nux vomica, is a good combination. The unpleasant taste of the phosphorus has been overcome by being made into sugar-coated or gelatine-coated pills. I frequently prescribe a pill containing phosphorus gr. $\frac{1}{50}$, with extract of nux vomica gr. $\frac{1}{8}$ thrice daily, with the happiest results. These pills can be obtained of any reliable druggist. This despondency is apt to occur in those who have been overworked mentally, or are harassed by business cares, or who suffer great mental anxiety. If in addition to these symptoms there be sleeplessness, I employ the following pill:

R Camphoræ pulveris, gr. xxv.
Ext. cannabis Indicæ, gr. x.
Ext. hyoscyami, gr. xx.

M. Divide in pill No. x.

Sig. One at night. Repeat in two hours if necessary to produce sleep.

It is important to attend to the general health of the patient. Remove all causes of excitement; encourage exercise in the open air; let the food be simple, but nutritious; let the sleeping room be large and well ventilated; in short, let the patient be surrounded by the best possible hygienic influences.

Hemicranie,' Virchow's *Archiv*, Bd. lix., 315. [Some other references will be found in the New Sydenham Society's *Biennial Retrospect*, 1873-74.—REP.]

* A Lecture delivered at Bellevue Hospital Medical College. (From the *New York Medical Record*.)

These general remarks will apply to almost all forms of headache.

Sick Headache.—I usually recognise two forms of sick headache (so-called); the one neuralgic in character, as hemicrania and trifacial neuralgia, the other a dyspeptic headache. In the neuralgic variety, the pain in the head precedes the nausea, while in the dyspeptic variety the pain in the head succeeds the dyspeptic symptoms. In the neuralgic, vomiting does not relieve the pain, while in the dyspeptic an emetic or laxative often relieves the pain in the head by removing the cause. In addition to the treatment given in a previous lecture for neuralgic headache, which often occurs at intervals of a few days, or a week or two, sometimes coming on at sunrise and disappearing at sunset, I have good results from the use of guarana, or paullinia sorbilis, as it is sometimes called. I give it usually in powder, fifteen grains every fifteen minutes, until six doses have been taken. It is best given in a little sweetened water; and, if six doses do not relieve, do not continue it; it will probably not relieve. It is well to give these powders in any headache (not malarial) of long standing and prone to return at certain intervals.

Malarial Headache.—Malarial poison may produce pain in any portion of the head, but the most frequent locations are the suboccipital region, the frontal, and on either side (hemicrania). Begin your treatment by the use of quinine. If distinctly periodical, give ten or fifteen grains two or three hours before the expected attack. It may be necessary to push the quinine in divided doses until cinchonism is produced, and kept up for several days, and then gradually diminish the dose. If the pain still continues to recur, and it frequently will, resort to arsenic and belladonna, five-drop doses each of Fowler's solution and belladonna tincture, after meals, increasing the Fowler's one drop each day, until œdema arsenicalis is produced. This will seldom fail to give relief.

I have found the following prescription beneficial in a headache dependent on gout:

R Vini colchici seminum, ʒij
Lithii bromidi, ʒss.
Syr. zingiberis, ʒss.
Aq. cinnamonii, q. s. ad ʒvj

M. Sig. ʒss. in a tumbler of Vichy water every four hours.

Such patients will be benefited by the regulation of hygiene, tonics, and a partial discontinuance of stimulants, particularly those which have been found by experience to aggravate the gouty symptoms.

Syphilitic Headache.—It is hardly necessary that I should tell you that the headache of syphilis is more severe at night, and is quite apt to awaken the patient after twelve by its increasing severity. The use of calomel in one-tenth grain doses every hour, for twelve hours immediately preceding the time that it awakens the patient, gives more rapid relief than the ordinary constitutional treatment. The calomel treatment may be continued for two or three days, and then stopped and iodide of potassium given. I usually begin the iodide in fifteen-grain doses after meals, and gradually increase it until iodism is produced or irritation of the stomach occurs, provided the symptoms do not yield earlier. It may be necessary to push it to 350 or 400 grains a day before the symptoms yield.

Rheumatic Headache.—The headache of rheumatism is characterised usually by tenderness of the

scalp, which is increased on pressure or motion. Use the mild faradic current on the scalp, and internally the following:

R Potassii iodidi,
Ammonie muriatis, ʒā ʒjss.
Infusi humuli, ʒvj

M. Sig. ʒss. four times a day in a wineglass of water.

In some cases of rheumatic headache, which have not yielded to the above treatment, I have found bromide of ammonium in twenty-grain doses every two hours effectual.

Uræmic Headache.—There is another form of headache which is of great importance as a symptom of serious disease. The pain in the head may be the first evidence you will obtain that there exists renal disease, and that you really have to deal with uræmic headache. The judicious plan of treatment in such cases has for its object the removal of the abnormal amount of urea from the system. To accomplish this, you may call into action one or all of the three great emunctories of the body, the kidneys, the intestines, and the skin. Make the kidneys act if you can; apply dry cups over the region of them, and give internally the following:

R Potassæ acetatis, ʒvj
Infusi digitalis, ʒvj

M. Sig. ʒss. every third hour.

The infusion should be made from fresh English leaves. Give this until the kidneys act freely, if you can make them do it within twenty-four hours. You cannot always rely on this, however. If the kidneys do not act freely, and the headache be not relieved within twenty-four hours, give a saline cathartic. A treatment almost domestic, and often very effectual, is to put an ounce of cream of tartar in a quart of water, and have the patient drink this in eight or ten hours. It acts both as a diuretic and cathartic. Do not use hydragogue cathartics unless convulsions be threatened; they are too irritating to the intestinal canal. Some prefer to eliminate the urea by the skin. This can be done by diaphoretics and the hot, moist, or dry air bath. Do not think that you must use diuretics, cathartics, and diaphoretics in all cases of Bright's disease; use them where there is deficient quantity of urinary secretion, and where you have reason to believe urea is accumulating, and that you can relieve the patient by ridding the system of it. There are other causes of headache in Bright's disease which, I believe, occur independently of the presence of an abnormal amount of urea in the blood, and yet which are dependent on the results of the kidney-disease. These causes may be anæmia, neuralgia, œdema of the brain itself, serous effusion into the ventricles, and, in acute Bright's disease, cerebral congestion in addition to accumulation of urea. Under the last condition, if the headache be very severe and convulsions threaten, take blood, if the patient's condition will admit of it. Take twelve to twenty ounces, if necessary to relieve distressing symptoms. The best way to take it is by means of wet cups over the region of the kidneys.

If the patient be anæmic, improve the general condition by the use of tonics, good nutritious diet, stimulants, exercise in the open air, etc.

If the headache be dependent on serous effusion into the ventricles, or on cerebral œdema, here too improve the vitiated condition of blood and stimulate the heart and kidneys by acetate of potash and infusion of digitalis. There is apt to be with this effusion and œdema general anasarca.

The Headache of Acute Alcoholism, or inebriety, follows a debauch. The first indication is to remove the alcohol from the intestinal canal. For this give of rhubarb and magnesia calcined each a half drachm, and then give the following :

R Spiritus ammoniæ arom. ʒij
Tincturæ camph. ʒjss.
Tincturæ hyoscyami, ʒjss.
Spiritus lavandulæ comp. q. s. ad ʒij

M. Sig. ʒj. every hour until the headache is relieved, and then give capsicum gr. ij and quinine gr. iij before each meal for several days. If there be sleeplessness, give

R Sodii bromidi, ʒss.
Chloral. hydrat. ʒjss.
Syrupi aurantii cort. ʒss.
Aquæ, ʒijss.

M. Sig. ʒss. at night, repeat in two hours if necessary to produce sleep.

Dyspeptic Headache.—Dyspepsia is a frequent cause of headache. If there be indigestible food in the stomach, and it have been there some time, give an emetic, as mustard and warm water, or sulphate of zinc gr. xv., and remove it. If there is evidence of indigestible food in the alimentary canal beyond the stomach, give gr. xx. of rhubarb and magnesia each, and remove it from the bowels. If the headache be frontal, and the pain be located immediately over the eyes, give dilute nitromuriatic acid in ten-drop doses, well diluted, after meals. If the pain be located about the roots of the hair, give an alkali before meals, as gr. xx. of bicarbonate of soda or magnesia. The dyspeptic headache oftentimes is not confined to these regions, but spreads over the entire head. In such cases I combine an acid with an alkali, and add to these nux vomica, as in the following prescription :

R Sodæ bicarbonatis, ʒjss
Acidi nitro-mur. diluti, ʒij
Tinct. nucis vomicæ, ʒjss.
Syr. aurant. cort. ʒvj
Aquæ, q. s. ad ʒvj

M. Sig. ʒss. after meals in a wineglass of water.

If there be gastric pain, a mild counterirritant, as a mustard plaster to the epigastrium, will often relieve the pain in the head as well as the pain in the stomach. If flatulence be a troublesome symptom, give the following :

R Bismuthi subcarbonatis, ʒjss.
Tinct. nucis vomicæ, ʒjss.
Tinct. cardamomi comp.
Spiritus lavandulæ comp. aa q. s. ad ʒiv.

M. Sig. ʒij. before meals in a wineglass of water.

If there be constipation, the following pill may be given, one in the morning :

R Aloes pulv. ʒss.
Ext. nucis. vomicæ, gr. v.
Ext. belladonnæ, gr. iv.

M. Div. in pilulas xv.

In some forms of headache associated with stomach indigestion I have found small doses often repeated of tincture of nux vomica effectual. I give a single drop every fifteen minutes, and continue this two or three hours if necessary. In other cases, where the headache comes on soon after a meal, and seems to depend on delayed stomach digestion, large doses of pepsin are effectual. Give a half drachm of saccharated pepsin in a wineglass of sherry wine, three times a day, and let it be taken during meals.

Congestive Headache.—Cerebral congestion as a cause of headache may be divided into two varieties, active and passive. These demand almost directly opposite plans of treatment. In the active variety the patient should be kept in a darkened room, per-

fectly quiet, cold and evaporating lotions applied to the head. A saline cathartic may be given, and the following prescription :

R Sodii bromidi, ʒjss.
Fl. ext. ergot, ʒjss.
Syr. zingib. ʒss.
Aq. aurant. flor. q. s. ad ʒiv.

M. Sig. ʒss. every two hours.

If the skin be hot and dry, and the pulse full and rapid, give two drops of Fleming's tincture of aconite root every two hours, until the heart's action is sensibly diminished. Sometimes a hot mustard foot-bath will give relief.

The passive congestive variety demands a different mode of treatment. In many cases this variety is found associated with cardiac disease, and most frequently where there is predominant dilatation. Hypertrophy gives rise to the active variety. Improve the condition of the blood by the use of iron, quinine, bitter tonics, alcoholic stimulants, good food, and stimulate the heart's action by the use of the following :

R Tinct. digitalis, ʒij
Spirit. amm. arom. ʒvj
Spirit. lavandulæ comp.
Syr. simp. aa q. s. ad ʒijj.

M. Sig. ʒj every four hours.

Anæmic Headache.—Cerebral anæmia produces a headache, which is often mistaken for the passive cerebral congestive form. It is often associated with general anæmia, nervous exhaustion, and may occur in heart disease, in consequence of enfeebled heart power, such as is met with in enlargement with dilatation, fatty degeneration, and myocarditis. Improve the general condition of the patient, and stimulate heart's action as recommended in the passive cerebral congestive variety. Nitrite of amyl will relieve the immediate headache. Let the patient inhale three to five drops of it on a piece of cotton, placed within one nostril while the other is held closed. When associated with nervous exhaustion, I employ the following :

R Strych. sulph. gr. ss.
Tinct. ferri chloridi ʒij.
Glycerinæ ʒss.
Infusi gentian. q. s. ad ʒvj.

M. Sig. ʒss. after meals, in a wineglass of water.

A word as to alcoholic stimulants. These are beneficial in headache dependent on cerebral anæmia. Champagne is a specially favourite form, and is much relished by those who suffer from nervous exhaustion. You should use caution in recommending it to such patients, as it may lead to serious results. Give it always as a remedy, and not as a beverage. A safe plan is to recommend brandy, a tablespoonful after each meal, and limit the champagne to one glass, and let it be taken with the dinner.

Cerebral tumours give rise to headache, often severe. In all cases of cerebral tumours, give iodide of potassium ; for it cannot be safely said that in any given case the tumour does not depend on syphilis, and by administering the remedy you give the patient the benefit of the doubt.

There is reason to believe, too, that patients with cerebral tumours, dependent on other and unknown cases, are benefited by the use of iodide of potassium. I have previously given you directions as to the method of giving the iodide. Sometimes the pain is so severe that you are justified in resorting to opium to relieve it. If there be much sleeplessness, give sleep by the use of the bromide and chloral mixture.

The headache of cerebral softening may be palliated by opium and rest. Such patients should have the best possible hygienic surroundings. If there be sleeplessness and much irritability of the nervous system, the combination of bromide with chloral is indicated. Ergot has been used for the relief of the headache, in these cases, by those having charge of insane asylums, where this condition is frequently met with, and the testimony is in its favour as a valuable remedy. It is usually given in large doses, beginning with 3j of fluid extract, three times a day, and gradually increasing to 3ss.

Almost all cases of increase of temperature of the body above 103° are attended with headache. To relieve it reduce the temperature, according to the plan given in a previous lecture; apply cold and evaporating lotions to the head, and keep the patient free from noise and excitement. A full opiate will often relieve such a headache, save the patient much suffering, and effect favourably the progress of the fever.

The mere mention of worms in the alimentary canal, hæmorrhoids, uterine and ovarian disturbance, and optical defects, as causes of headache, will suggest the remedy.

SCHWARTZ ON THE TEMPERATURE IN PHTHISIS PULMONALIS.

About fifty-two pages of the *Verhandlungen der Physikal-Medicin. Gesellschaft in Würzburg* (Neue Folge, Band ix. Heft. 3 and 4) are occupied with a paper by Dr. Albert Schwarz, of Türkheim in the Palatinate, on the types of fever in pulmonary phthisis. The material is from patients in the Julius Hospital, by the kind permission of Dr. Gerhardt. The temperatures were taken in the axilla, at 6 A.M. and 6 P.M. In very interesting cases, Dr. Gerhardt had temperatures taken every three hours (at 6, 9, 12, etc.) or eight times daily. Dr. Schwarz remarks that pulmonary consumption is nearly always attended with fever. Cases free from fever in their later stages are extremely rare. This fever is, however, rarely typical in the same sense as that of croupous pneumonia, or abdominal typhus. It is rare to find two phthisical cases with exactly the same sort of curves. The same anatomical lesions induce in one case moderately febrile temperatures, in another high fever. Sometimes the evening temperatures are highest, at other times the morning. Sometimes there are two exacerbations in the same day. In short, all possible varieties are met with. The causes of pyrexia in phthisical patients are (1) morbid processes originating in localised lesions, (2) secondary disorders of the whole system originating in these, (3) one or other of the common complications of phthisis, (4) individual peculiarities; at all events, the varieties in the height of the fever are partly due to these idiosyncrasies.

If we look at these conditions in another way, we may first consider the local changes in the lungs of such patients:—suppuration, and inflammatory products, perhaps undergoing retrograde metamorphosis. These purulent or disintegrating matters are absorbed by lymphatics and blood-vessels. Hence arises a fever of 'purulent infection,' analogous to that set up by suppurative processes elsewhere. From these conditions we get (a) different degrees of fever at different times of the day; when absorption is most active we get exacerbations, and *vice versa*. (b) The course is irregular all through the complaint; for

example we get (a) great exacerbations when these processes go on rapidly, and there is increased absorption, and, (β) stages free from fever, explained by the local stand-still during calcification, etc. In this way the fever is checked. (γ) The influence, or want of influence, of remedies upon the disease, will affect (or otherwise) the course of the fever. 2. As to the reaction on the system, we know but little; certainly there are diminished oxydation, diminished (normal) warmth-production, diminished combustion of albuminous and other bodies, defective nutrition, and the like changes. These things rather tend to lower than to raise the temperatures. 3. Amongst complications, inflammatory attacks, pleurisy, bronchitis, pneumonia, etc., must not be forgotten. 4. As to idiosyncrasies, the author refers doubters to analogy, instancing the urethral fevers met with in certain persons from the passage of a catheter, etc. The author then proceeds to consider his own observations on phthisical temperatures, and arranges them as follows.

A. *Morning temperatures* are the most important in prognosis. These are (1) either normal, or (2) exhibit morbid disturbances. In the latter case they are either (α) subnormal, or (β) moderately high, or (γ) highly febrile temperatures. He gives the following table:

Cases Discharged Improved		Fatal Cases
Subnormal Temperatures sometimes occur in both classes		
Normal		
96°8' to 97°7' F.	2 cases	6 cases
97°8' to 98°6' F.	7 "	4 "
98°7' to 99°5' F.	10 "	14 "
99°6' to 100°4' F.	2 "	9 "
Febrile		
100°5' to 101°3' F.	4 cases	3 cases
101°4' to 102°2' F.	1 "	9 "
102°3' to 103°1' F.	0 "	4 "
High Fever		
103°2' to 104°0' F.	0 cases	13 cases
104°1' to 104°9' F.	0 "	1 "
105°1' to 105°8' F.	0 "	1 "

We thus see, for morning temperatures twenty-one normal (or 81 per cent.) and five febrile or highly febrile (or 18 per cent.) amongst those who were discharged improved in health; whereas in the fatal cases, the respective numbers are thirty-three normal and thirty-one febrile and highly febrile, or 51 and 49 per cent.

B. *Evening temperatures* may be divided into the same classes as the morning. We have the following table given us of the same number of cases (twenty-six discharged as improved, sixty-nine fatal ones).

Examining these in the same way as we did the morning temperatures, we find amongst the cases which improved, 38·5 per cent. with normal, and 61·5 per cent. with febrile and highly febrile temperatures. Of the fatal cases we find only 16 per cent. with normal, and 84 per cent. with febrile and highly febrile temperatures. Temperatures above 105°8' F. are exceptional.

C. *Subnormal temperatures* are either, (1) a sign of collapse, which is so common, that subnormal temperatures may be regarded in most cases as identical with terminal temperatures—only remembering that, (2) subnormal temperatures often occur, in the morning especially, with increased body-weight, and good general health, especially in the early stages

of the lung disease. The lowest subnormal temperature in our charts is 90° F. (an evening observation); then follows a morning one of 90.2° F., an evening

Cases which Improved	Fatal Cases
Solitary Subnormal Temperatures occur in both classes.	
Normal	
96°8' to 97°7' F.	0 cases
97°8' to 98°6' F.	8 "
98°7' to 99°5' F.	4 "
99°6' to 100°4' F.	3 "
Febrile	
100°5' to 101°3' F.	5 cases
101°4' to 102°2' F.	9 "
102°3' to 103°1' F.	22 "
Highly Febrile	
103°2' to 104°0' F.	3 cases
104°1' to 104°9' F.	14 cases
104°1' to 104°9' F.	0 "
105°1' to 105°8' F.	3 "
105°8' and over	isolated observations in both classes
Total	26
	69

one of 92.3° F., several of 93.2° , and so on. The very low temperatures are generally just before death. In one case, the first subnormal temperature occurred twenty-six days before death. It amounted to 96.4° F.

Of the Types of Fever in Phthisis.

The temperature in phthisical cases is either, (1) normal which is rare, or (2), febrile. As regards the latter, the fever may occur at different times of the day, may remain constant, show longer or shorter exacerbations, and periods of deservescence of more or less length, and, in short, show various types. The commonest form is, in twenty-four hours, one period free from fever, alternating with an ascent above 100.4° F. the rise being in the morning, or in the evening—less often at odd times. More rarely, two febrile periods alternate with one fever-free one; or two periods free from fever with one febrile in the twenty-four hours—Lebert's unbroken type (*typus infractus*). In still rarer cases three rises of temperature, or even more, may be seen. Sometimes, indeed not very rarely, we meet with cases of continual fever—that is cases in which the remissions never go below 100.4° F. Thus there is always fever. As regards the observations at two fixed times of the day, we find the charts thus made by a combination of morning and evening temperatures present the following four types.

A. The type of normal temperatures; in other words, both morning and evening temperatures are within normal limits, the evenings being a few tenths above the morning (seventeen cases).

B. Type with slight evening fever, with normal (but seldom subnormal) morning temperatures (twenty cases).

C. Type of more intense evening fever, in which we get :—C¹. Morning temperature normal or subnormal, so that the charts resemble those of an intermittent quotidian or tertian fever. C². The morning temperatures are febrile also, but a few tenths lower than the evening ones, thus resembling a continuous remittent fever (fifty cases.)

The types B and C are members of one family, and are merely separated for systematic purposes.

D. The *inverted type*.—In this the morning temperatures are febrile, often extremely so, and the evening normal, or only moderately febrile. Here

we get a *febris remittens quotidiana* and a *febris remittens*, only the acme is in the morning hours (three cases).

As a fifth type may be reckoned the *Typus inversus intercurrentis*, the definition of which will be given afterwards. These types run one into the other, and are seldom constant. There is no very fixed anatomical or pathological relation between symptoms and lesions and these types.

Remarks on these Typical Forms.

A. The normal type or curve resembling that of health, occurs (a) when the local disease has only made slight progress; (b) When the disease is checked, or has come to a standstill, either spontaneously or from treatment; (c) Towards the close of the disease, with marastic symptoms, or in consequence of a lower grade of vitality being reached; (d) Hæmoptysis causes temporary returns to normal temperatures; (e) The author met with four complicated cases, in which there were normal temperatures; but the phthisical processes consisted in induration of the lung.

B. The type of mild evening fever, with normal morning temperatures. This type affords us little aid in prognosis, as it occurs both in cases which improve (nine cases) and in those which end fatally (four cases). We may, however, say (1) that it may occur at the very beginning of the disease (beautifully shown in two cases); 2. It may prevail all through the disease [one case shows this very well]; 3. It may occur as a terminal form of the fever; 4. It may occur, intercurrently, after hæmoptysis (three cases).

C. The type with great intensity of evening fever. This, as has been already said, occurs in two different forms—one like a quotidian intermittent fever, with evening exacerbations, and normal or even subnormal morning temperatures; and the other as a continuous fever with more or less remission in the mornings. Of these we may remark (a) an intermittent type with rather high evening temperatures, which are often above 104° Fahr., the morning temperatures being generally between 96.8° and 98.6° Fahr. But subnormal and slightly febrile temperatures sometimes occur in the mornings. This type with high evening temperatures is pretty constant where it once occurs. The prognosis is bad. (b.) The remittent type is by far the commonest of all. The evening temperature is often febrile, it may be highly febrile. There is a remission during the night, but seldom complete apyrexia. The remissions seldom amount to more than one degree Centigrade (1.8° Fahr.).

This type is often chronic as regards the duration of the cases. Yet the cases are sometimes acute as regards wasting and other symptoms. One of our cases lost 20 grammes (nearly $\frac{3}{4}$ oz.) of body-weight daily, for three months continuously. Although the actual temperatures attained are never very great, indeed seldom above 103.1° Fahr., yet the prognosis is almost always unfavourable.

D. The *typus inversus*, or type in which the morning temperatures are febrile or highly febrile, whilst the evening temperatures are normal or only febrile, thus resembling an intermittent in which the morning hours exhibit the acme as regards fever. The reasons of this peculiarity are difficult to find. Jochmann ascribes it to the use of digitalis, but this will not explain our cases; indeed, it must be confessed that digitalis has but little effect on the tem-

peratures. This type is rare, only three out of ninety cases exhibiting it.

E. The intercurrent inverted type. Nearly all the cases exhibit occasional deviations from their prevailing type. In many of the cases we find that the time of day which used to be the fever period becomes for a time the period of freedom from fever, and *vice versa*. This intercurrent inversion of the typical form occurs in all varieties of the fever, as will be seen from the following table.

Types	No. of days observed	Days of Inversion of type occurring intercurrently	Percentage of such
A.	453	80	18
B.	611	81	13
Ca.	300	8	2.6
Cb.	1651	263	16
D.	197	30	16
Total . .	3212	462	14

An inversion of the type is thus seen to occur about once a week, in all the cases together.

This inversion of type appears to be a pet subject with Dr. Schwarz, since he devotes nearly six pages to it. The rest of the paper is occupied with remarks on collapse temperatures; on the subjective feelings of warmth in phthisical patients; on the relation between temperature and the frequency of the pulse [in which the author, in the reporter's opinion, is too much inclined to undervalue the indications afforded by the pulse]; on perspiration in relation to the fever of phthisical patients, and on the relations of hæmoptysis to the fever. In all this there is very little novelty, more space being given to criticism of Lebert and other authors than to original work.

The following table exhibits the prognostic value of the several types.

Types	Cases with Improvement	Cases with Fatal Termination
A. Normal temperature	9	7
B. Moderate evening temperatures	8	12
Ca. Intermittent type	1	7
Cb. Remittent „	7	36
D. Inverted „	1	2
Totals	26	64

The author's general conclusions from these figures are as follows. 1. The majority of cases of phthisis end fatally; but, 2. The prognosis may be regarded as favourable in about half of those cases in which the temperature is either normal or mode-

Types	Cases with Improvement	Cases with Fatal Termination
A. and B.	17	19
Percentage	47	53

rately febrile, as shown by the figures in the last table. 3. The prognosis is a very unfavourable one when for some time the patient shows a fever-curve with intermittent, remittent, or inverted type. The most unfavourable of all is the pure, hectic, intermittent curve. As regards the effects of remedies, the author speaks very disparagingly. He has no word of praise for any of them, except atropia, which he admits to have a favourable effect in lessening the excessive perspirations, and on the general comfort of the patients. W. BATHURST WOODMAN.

ANATOMY AND PHYSIOLOGY.

DUPUY ON THE LOCALISATION OF MOTOR CENTRES.—At a meeting of the American Neurological Association (*New York Medical Record*, July 15), Dr. Eugene Dupuy, of New York, read a paper upon the above subject, which may be summarised in the following propositions.

The cortical substance of the brain was not excitable by any means, either physical, chemical, or mechanical.

The effect of electricity, when applied to the surface of the brain, was not localised, but diffused, and the motor results obtained when electricity was used were not due to the direct action of the irritant, but were altogether reflex.

No part of the brain-substance was excitable except the nerve-fibres, and there was no way by which nerve-cells could be excited except by exciting the nerve-fibres with which they were connected.

When electricity was applied to the cortex, motion might take place, but it was not the nerve-cells themselves which were put into action, as proved by experiments. The cranium of an animal was laid open, a point made sure, which, when irritated, gave rise to certain motions, and then the pia mater was rendered opaque by means of hot iron; but motion followed the application of an irritant, the same as before. The wound was then allowed to close, and at the end of a month the electrodes were applied over the dura mater covering the same spot, and motion was produced upon the same side of the body. The dura mater was then divided, and the white patch in the pia mater exposed, and then, when the electrodes were applied, slight motion followed, but not so marked as before. The surface of the part was then dried by means of blotting paper, and the electrodes applied, but no motion followed. The sclerosed patch of pia mater was then removed, and the surface dried, but no motion followed the application of the electrodes.

If motion did not take place in the second series of experiments, it was not from lack of cortical substance, because the fibres below were found to be healthy when examined with the microscope.

It was then clear that the motion was not due to disturbance of the nerve-cells, nor to disturbance of the nerve-fibres, except those in close relation with the blood-vessels. Dr. Dupuy then undertook the examination of the structure of the brain-tissue and pia mater; and he had found that the only points in the cortical substance where motion could be produced by the application of an irritant, were those supplied by vessels which came from the pia mater, and dipped deep into the substance of the brain, and had nerve-fibres accompanying them. He be-

lieved, therefore, that there was a nervous connection between the pia mater and the fibres from the spinal cord which was continuous, and that motion was produced through that connection when an irritant was applied to the pia mater.—In the discussion which followed, Dr. J. W. S. Arnold, of New York, asked Dr. Dupuy what current he employed to stimulate the brain—the induced or the constant current, or the primary or secondary induced current? Dr. Dupuy replied that it made no difference with regard to the current employed. Dr. Arnold was so convinced the diffusion of the induced current was so great that its action could not be limited, whereas the constant current could be limited, and the exact point from which the action came could be determined. He had been able, by means of the constant current, to decompose brain-tissue to such an extent that motion in certain muscles or groups of muscles, in response to the electrical irritant, could not be reproduced; and that when such tissue had been examined microscopically, the structure had been found to be entirely changed. He had also found that when certain points in the brain, which seemed to have presiding power over definite sets of muscles, were destroyed by means of the constant current, motion could no longer be produced in response to the electrical irritant. The action of involuntary muscular fibres was slow, but the motions produced in response to an electrical irritant applied to the surface of the brain were instantaneous. He had records of movements following immediately upon the application of the irritant; and not only so, but that he had measured the difference in time which elapsed before motion was produced when the irritant was applied to the involuntary muscular fibres of the blood-vessels in the brain, and when it was applied to the cortical substance and gave rise to motion in the voluntary muscles in the limbs of the animal, and that there was a very appreciable difference in the length of time which elapsed before motion was produced in the two instances. In all his experiments, also, the brain-surface was kept free from moisture.—Dr. Jewell thought that, although Dr. Dupuy's paper was interesting with respect to the question of the mechanism by which the excitation led to the contraction, it did not militate greatly against the doctrine of localisation of function, but was simply another method of explaining how the contraction was brought about. If the contraction was due to a modification in the nutrition of the part irritated, that view was just as favourable as any other to the doctrine of localisation.

SHEPHERD ON ANATOMICAL ABNORMALITIES.—In a paper in the *Canada Medical and Surgical Journal* for August Dr. F. J. Shepherd, Demonstrator of Anatomy in the McGill Medical College, gives an account of anatomical abnormalities observed in the dissecting room during the winter session of 1875-76. The notes were taken on the spot from thirty-six bodies dissected. Dr. Shepherd does not describe all the variations which occurred, but only those which attracted most attention at the time.

Osseous System.—In one subject (a squaw) there were three floating ribs on each side.

Muscular System.—There was one example of the posterior belly of the digastric and the stylo-hyoid muscle passing under cover of the external carotid artery. This occurred on both sides of the same

subject. The stylo-hyoid muscle passing between the external and internal carotid is, Dr. Shepherd says, of no very great rarity, although it is stated in the *Guy's Hospital Reports* for 1868, that it did not occur once in 158 cases. He has never seen a case of the posterior belly of the digastric passing under cover of the external carotid recorded. In this subject the course of the external carotid was very superficial, in consequence of the variation. The pectoralis minor arose nearly as often from the second, third, and fourth ribs, as from the third, fourth, and fifth, and that the coracobrachialis muscle was only perforated by the musculo-cutaneous nerve in about two-thirds of the cases. No case of abnormality of the muscles of the back or face was noticed. In one subject (a Frenchman), the muscles of the face were developed in an extraordinary manner, so as to be easily dissected out by a first year's student. In this subject the platysma myoides was nearly as strongly developed as the corresponding muscle in the horse. In three examples, the biceps brachii arose by three heads, all occurring on the right side. In two of the cases the third head arose just below the insertion of the coraco-brachialis; in the third case, it arose between the two fleshy digitations of brachialis anticus muscle. In another case there was a slip given off from the biceps which joined the pronator radii teres muscle; this slip gave origin to the greater part of the bicipital fascia. There was one example of an extra extensor secundi internodii pollicis arising from the radius opposite the origin of the proper extensor secundi internodii pollicis. In this subject the origin of the extensor indicis was much more extensive than usual. In one example, a slip of muscle was given off from the extensor ossis metacarpi pollicis, and joined the abductor pollicis. In one case in which the palmaris longus was absent, there was absence of the gemellus superior on both sides in one subject. In one subject the gastrocnemius muscle of the left leg was most extraordinary in having its external head completely wanting. This occurred in a female. On dissecting off the integument and fascia of the left leg, the first thing that came into view was the little plantaris muscle. The usual point of origin of the outer head of the gastrocnemius was quite bare, the bone merely being covered by a little fat. The internal head was of the usual size. Dr. Shepherd believes the case to be quite unique. The muscles of the shoulder and hip were quite normal in all the subjects. In one subject there was a separation of about two inches at the insertion of the two recti abdominis muscles. They commenced to separate about the umbilicus. There were two examples of absence of the plantaris muscle, in each case occurring on the left side.

Arterial System.—In one case, the superior laryngeal artery arose directly from the external carotid instead of from the superior thyroid; it was about twice the usual size. The arch of the aorta was abnormal in one case only. In this case the left vertebral artery was given off directly from the arch. In the same body there was a thyroidea ima artery given off from the innominate.

There were four examples of high division of the brachial artery, all occurring on one side of the body only. In two, the division took place just below the insertion of the deltoid muscle. In a third, the division occurred in the latissimus dorsi muscle. The branch on the radial side afterwards became the ulnar by crossing the radial about the bend of the

elbow, and then continued on as usual. In the fourth case the artery given off on the ulnar side afterwards became the radial, by crossing the ulnar just above the bend of the elbow. In this case the radial recurrent artery was given off from the ulnar. There was one low division of the brachial, the division taking place at the lower border of the pronator radii teres muscle. In this case the ulnar artery was quite superficial throughout its whole course, and the interosseous, radial, and ulnar recurrent arteries were given off from the brachial. There was one example of a large median artery being given off from the brachial and accompanying the median nerve, supplying the same number of fingers ($3\frac{1}{2}$) as the median nerve, and taking the place of the ulnar in forming the superficial palmar arch; the ulnar artery in this case was smaller than usual, and accompanied the ulnar nerve, supplying the little finger and half the ring finger like it. The deep branch of the ulnar communicating with the deep palmar arch was given off as usual. This peculiar distribution of the arteries of the forearm and hand occurred on both sides in the same body. There were three examples of the obturator artery being given off from the deep epigastric. Two occurred on the right side and one on the left. The obturator artery in all three cases passed to the outer side of the femoral ring. In one case the obturator artery gave off a very large pubic branch; all three examples occurred in females. In four cases the external circumflex artery was given off from the superficial instead of the deep femoral; three cases occurred on one side only. There was one example of the peroneal artery forming the dorsalis pedis, and to a certain extent taking the place of the anterior tibial. This peroneal artery was of large size, and after supplying the peroneal muscles it pierced the interosseous membrane, and appeared on the front of the leg between the extensor proprius pollicis and extensor longus digitorum muscles, continuing on as the dorsalis pedis artery. In this case there was a small anterior tibial artery which supplied the anterior tibial muscles, and ended a little below the middle of the leg.

Nervous System.—There were two cases where the musculo-cutaneous nerve was given off from the median below the insertion of the coraco-brachialis, this muscle being supplied in the one case by a few filaments from the outer head of the median, and in the other by a special branch from the outer cord of the brachial plexus given off high up. In both cases the brachialis anticus and biceps muscles were supplied by the musculo-cutaneous nerve, as usual. There were two examples of the median nerve passing behind the brachial artery. There were seven cases where the great sciatic nerve divided high up; in all these cases the external popliteal nerve pierced the piriformis muscle. Three of these cases occurred in both sides of the same body.

Internal Organs.—There was one case of horse-shoe kidney. There were two examples of the descending colon having a meso-colon; in one case this meso-colon was about $1\frac{1}{2}$ inches long, and in the other (a squaw) the meso-colon was $3\frac{1}{2}$ inches; in this case the descending colon was about ten inches longer than usual. In both these cases, the peritoneum would have been wounded in the operation of colotomy. In three subjects (females) the sigmoid flexure of the colon was continued across, from about the middle of the iliac fossa on the left side, to the sacro-iliac synchondrosis of the right

side where the rectum commenced, and was normal for the rest of its extent, going from right to left, however, instead of from left to right. In two of these cases the lower transverse colon was two feet long. Several cases in which there was a meso-rectum were also noticed.

COUTY ON THE INFLUENCE OF CEREBRAL ANÆMIA ON THE CIRCULATION.—At the meeting of the Société de Biologie on August 5, M. Couty states that he had studied in M. Vulpian's laboratory the influence of cerebral anæmia on the cardiovascular functions. The following were the results of his researches. If the anæmia involved all parts, brain and mesocephalon there, were, 1. Considerable augmentation of the arterial tension, which was doubled and even in certain cases trebled; 2. Slowness of the pulse which, from 180 to 140 pulsations a minute, fell to 40 or 30.

After lasting some time, 8 to 10 minutes at least, these phenomena ceased, the tension falling even below the normal.

If the anæmia involved only the anterior parts of the brain, the heart's action became slow, but there was no notable and lasting variation in the arterial tension. The retardation of the heart itself was less considerable than in the case of general anæmia of the encephalon.

W. DOUGLAS HEMMING.

ROEHRIG ON THE PHYSIOLOGY OF MILK SECRETION.—Dr. A. Roehrig (Virchow's *Archiv*, May 1876) observes that the results of his experiments on the secretion of milk show that there is a constant relation between the blood-pressure in the gland and the quantity of milk secreted. His method included acting on the nerves supplying the tissues of the organ by section and galvanism, and the administration of drugs which act upon the vascular tonus, such as strychnine, digitaline, caffeine, jaborandi, all of which increased the secretion, and chloral-hydrate, which reduced it; and finally, by increasing the blood-pressure in a curarised animal by temporarily suspending respiration.

ARNDT ON THE SIGNIFICANCE OF THE MEDULLARY NERVE-SHEATHS.—Dr. Rudolf Arndt (Virchow's *Archiv*, May 1876) says that a comparison of the facts derived from anatomical observations, human and comparative, and the results of clinical and pathological investigations, shows that the development of the medullary sheaths stands in direct proportion to the activity of the nerve-fibre. In the lower animals and in the embryo, many nerve-fibres are naked, and the development of the medullary sheath takes place by the formation of small round cells (*Kugelchen*), which arrange themselves around the nerve-fibre, and finally melt together to form a homogeneous sheath, which thickens by additional concentrically formed layers. He considers its formation to be due to functional irritation.

PATHOLOGY.

ESSENTIAL ANÆMIA.—The *Gazette des Hôpitaux* of July 18, reports a case of idiopathic anæmia, read before the Société Médicale des Hôpitaux, on the 14th, by M. Lépine. The patient was a woman, aged thirty-four, who, during her third pregnancy, began to suffer from diarrhœa and cough with mucous expectoration. She lost her appetite and colour, and her legs swelled. Soon after delivery, she presented a condition of extreme anæmia, without any sign of organic disease, though M. Lépine suspected the existence of cancer of the stomach. The diarrhœa was stopped by opiates, but the other symptoms increased. The number of red corpuscles, at first 909,000 in a cubic millimètre, continued to diminish, without any augmentation of leucocytes. [The number in health is over 4,000,000 per cubic millimètre.—*Rep.*] There were a systolic anæmic cardiac murmur, increasing pallor, anasarca and muscular weakness, with no pyrexia, no enlargement of spleen or lymph glands, no hæmorrhage or albuminuria. In less than two months after delivery the patient died. The number of red blood-disks per cubic millimètre, which had increased to 1,129,500, was 378,750 shortly before death, and the (vaginal) temperature was 34°·8° [94°·6° F.]

Except the fatty degeneration of the heart, usually found in these cases, and slight broncho-pneumonia, no lesion was found after death, and it is important to note that the marrow of the bones was examined, and found normal.

In the remarks on the case made by M. Lépine and other physicians present, reference was made to the cases published by Gusserow, Biermer, Immermann, Broadbent, and others, and also to the earlier observations of Addison and Wilks; but these seem to have been studied at second hand, for M. Lépine evidently does not know that this remarkable form of disease was accurately described by the late Dr. Addison, and distinguished from that to which his name has since been given. This fact has been fully stated by Dr. Wilks in the *Guy's Hospital Reports* for 1857 (p. 203), and by the present reporter in a paper in the sixty-fifth volume of *Virchow's Archiv*, and it only needs a reference to p. 212 of the Sydenham Society's edition of Addison's works to show how completely the symptoms and pathology of idiopathic anæmia are there described.

Some of the cases published by Lebert in 1858, mentioned in the July number of this journal (p. 291) may have been of the same nature, but he, like other observers, did not sufficiently distinguish essential or idiopathic anæmia from the various forms of chlorosis and symptomatic anæmia which occur in women. Trousseau's case (*Clinique Médicale*, tom. iii. p. 63), published in 1868, was contemporary with Biermer's paper, and preceded those of Gusserow

and Ponfick is also a doubtful one, and was not recognised by the eloquent lecturer as what is now called idiopathic or essential or progressive anæmia. —*Rep.* P. H. PYE-SMITH, M.D.

SEVESTRE ON RETROPERITONEAL CANCEROUS TUMOUR.—At a meeting of the Anatomical Society of Paris (*Le Progrès Médical*, August 19), Dr. A. Sevestre communicated the case of a woman, aged thirty-five, a sempstress, who was admitted into the Charité Hospital on October 29, 1875, on account of dyspeptic troubles and very severe pains in the epigastrium. The family history was unimportant. Until her marriage, at twenty-five years of age, she had always had good health; since that time she had suffered from pains in the stomach, beating of the heart, oppression, and scantiness of breath after running or much exertion, but the symptoms which troubled her most were troubles of the digestive organs, consisting of more or less acute pain after meals and a slowness of digestion.

On her admission, the patient complained almost exclusively of pains occupying the lumbar region and the abdomen, especially about the level of the umbilicus and epigastrium. The pains were compared to sensations of burning, tearing, and gnawing; from the loins and epigastrium they radiated towards the pelvis and the flanks, and in the other direction towards the thorax and neck. The pains were continuous, but there were occasional exacerbations of a very violent character, which coincided neither with a meal nor with any other appreciable cause: they existed during the night, and disturbed rest. Pressure did not increase them, nor were there any neuralgic points.

The appetite, though diminished, was not destroyed; digestion proceeded slowly, and the ingestion of food was followed by a sensation of weight and fulness, which lasted for some hours. There was no vomiting nor nausea. The tongue was scarlet, denuded of epithelium; the papillæ were very prominent; the passage of hot or irritating food caused a strong burning sensation. The stools were scanty, and the patient had for some time suffered from troublesome constipation. The belly was somewhat inflated, and palpation revealed, at the level of the epigastrium, in a horizontal line, and separated by an interval of two or three fingers' breadth, three tumours of the shape and size of a large chestnut; these tumours were indolent. The other functions were natural. The patient was thin, but maintained her colour, and had not the cachectic appearance usual in organic affections.

The patient succumbed on February 18, 1876. She had never had œdema.

On opening the abdomen, and removing the stomach and intestines, a tumour was found lying in front of the vertebral column, and extending between the stomach, transverse colon and spleen. From the anterior aspect of the tumour, fibrous bands passed to the different organs of the abdomen; at one point these adhesions assumed the form of a resisting bridle which passed from above downwards and from before backwards round the front of the colon, and caused considerable contraction. This band being divided, the wall of the intestines bulged out, and no further alteration was found in it. The same was the case with other parts of the intestine which at certain points had slight adhesion. The stomach was intimately attached to the tumour to the size of the palm of the hand about the middle of

its posterior aspect. The mucous membrane appeared healthy to the naked eye. The pancreas was entirely mixed up with the tumour, and could not be isolated; its situation could be determined only by some yellowish spots disseminated in the fibrous tissue, in which the microscope showed granulations without recognisable cells. The spleen at its internal aspect was firmly adherent to the morbid growth. Externally, there was only thickening of the capsule. The left kidney, at the root of the hilus, was also mixed up with the tumour. The right kidney was healthy. The liver was of normal size; on its anterior surface were three nodules of the size of a walnut, presenting all the appearances of cancer. The bile-duct and ductus communis were slightly dilated and filled with bile, but not obstructed. The uterus and genital organs were healthy.

On section the tumour presented an extremely clear fibrous appearance with lose and thin yellowish points; its tissue was extremely hard, creaked under the knife and showed no points of softening; a moderately abundant juice exuded on scraping. The microscope revealed cells of variable form and size, generally rounded and oval, rather larger than white corpuscles and having large nuclei provided mostly with a shining nucleolus. The arteries traversing the tumour were little altered; the corresponding vein however, and particularly the splenic vein, were obstructed. The lymphatic vessels and glands were lost in the tumour, so that it was impossible to find traces of them. Histological examination after hardening showed the tumour to be composed of a fibrous carcinoma. The alveoli were filled with the cellular elements above described and the trabeculae, very thick, were formed by a very dense fibrous tissue in the midst of which, here and there, were traces of fatty tissue. The morbid tissue would appear to have its origin in the subperitoneal connective tissue. The tumours of the liver and spleen were composed of carcinoma with large alveoli separated by very thin partitions.

The above case appears to be an example of a rare and little known lesion, described by Lobstein as retro-peritoneal cancerous tumour, and by Bayle and Cayol as abdominal cancerous masses. Developed in the subperitoneal cellular tissue in front of the vertebral column, these tumours increase towards the anterior region of the abdomen.

They may be situated in different parts of the cavity; more often they occupy the superior part and may simulate cancer of the stomach; or they may have their origin in the pelvis and interfere more or less with the functions of the organs therein. Histologically this constitution varies much. The various kind of carcinoma or sarcoma may occur; there may be cysts or the tissue may undergo softening and be the seat of hæmorrhage.

LAURENT ON FIBRO-MYOMATA OF THE KIDNEY AND FIBROUS TUMOUR OF THE UTERUS IN A WOMAN WHO DIED FROM SENILE GANGRENE.—At a meeting of the Anatomical Society of Paris (*Progrès Médical*, August 19), M. A. Laurent exhibited two specimens taken from a woman seventy-five years of age, who died from senile gangrene under the care of M. Charcot. At the necropsy, each kidney was found studded with small ovoid hard bodies, about the size of a lentil, situated between the parenchyma of the kidney and its capsule; removal of the cortex showed that these little lenticular bodies were inseparable from the

capsule, and were not adherent to the substance of the kidney, which in other respects was perfectly healthy. The patient had never shown any uræmic symptoms. A section coloured with picrocarminate plainly showed the muscular element, and made it evident that there were fibro-myomata. The uterus, on examination, was found very large, knotted, hardened in all parts except the neck, which was intact. Section in all directions showed a score of interstitial fibrous bodies, varying in volume from that of a walnut to that of a hazel-nut. One of these tumours, larger than the others, and having a diameter of four or five centimètres, occupied the posterior wall. The uterine cavity was reduced almost to nothing.

W. DOUGLAS HEMMING.

FRONMÜLLER ON TWO CASES OF IDIOPATHIC CANCER OF THE KIDNEYS.—Dr. G. Fronmüller, senr. (Betz's *Memorabilien*, Jahrgang xxi. Heft 4), says that a magistrate of his acquaintance was in the habit, about a year before his death, of pressing his left hand, or rather fist, on the lumbar region in walking, and also in standing. When asked why he adopted so remarkable a gesture, he said that it relieved a peculiar pain he felt there. The chief complaints from which he then suffered, being in his sixty-second year, and a strongly built man, were attacks of rheumatism, and particularly periodic attacks of dyspnoea, the latter was often extreme, in consequence of a fatty heart. In one of these attacks he suddenly and unexpectedly died. The lumbar pain had been supposed to be rheumatic, or due to hæmorrhoids. His urine was often examined, and nothing abnormal was discovered in it, perhaps because at that time the cancer had not invaded the pelvis of the kidney. At the *post mortem* examination, the heart was found large, both its ventricles dilated, and its muscular structure was flabby, and had undergone fatty degeneration. The commencement of the aorta was dilated; the liver was hyperæmic and fatty. The left kidney was somewhat enlarged, and contained a mass rather bigger than a pigeon's egg, growing from the cortical substance of one side into the kidney-fat, and on the other side extending into the pelvis of the kidney; resembling, when cut into, medullary sarcoma (*Markschwamm*). The right kidney was normal, and there was no other trace of carcinoma in the body. Two years ago, the same observer met with another case of cancer of the kidney, of far larger size, in the person of a weaver, aged fifty-six years, who was admitted into the hospital with some oedema of the feet, slight pain in the loins, and some not very severe constitutional symptoms. The urine contained neither albumen nor anything else abnormal. After a fortnight the oedema had vanished, and the pain in the loins was almost gone. At his own request he was discharged as 'relieved.' Six days afterwards he was again brought back to the institution. He had been attacked with extreme weakness and tendency to fall, much meteorism, and slight ascites; the left loin had become prominent, there was moderate oedema of the feet, and some pyrexia. The rapid development of these symptoms seemed difficult to explain, and they were attributed to retention of feces, etc. Early next morning the patient died. At the *post mortem* examination the lungs were found to be healthy, the heart somewhat enlarged, and the subject of fatty degeneration. The liver had also become fatty. The spleen was

small and flaccid. The left kidney was enlarged to five times its normal bulk, and was full of nodules of medullary cancer. The adjacent parts of the peritoneum and great omentum had similar nodules of soft fibrillated cancer. The rest of the body appeared healthy.

LOTZE ON A FATAL CASE OF JAUNDICE DUE TO CONGENITAL MALFORMATION OF BILE-DUCTS.—No. 30 of the *Berliner Klinische Wochenschrift*, July 24, 1876, contains the following case, reported by Dr. Konrad Lotze, of Osterode. He remarks that similar cases are rare, and that he has been unable to find one quite analogous.* The child referred to had a very delicate, anæmic, and strumous mother. The father (a master-mason) was strong and healthy. During the first three weeks of life the infant's skin had a slight yellowish tinge. There had also been slight diarrhoea. The icterode condition soon deepened into intense jaundice. At 3½ months of age, the child was much wasted, the skin was a deep yellow, flabby, and shrivelled, the conjunctivæ were of an olive green tint. The urine was turbid, greenish yellow, and contained fat, with much bile-pigment. The fæces were yellowish green. The liver was considerably enlarged. There was no special somnolence, fever, or retardation of pulse. The appetite and digestion seemed fairly good, though the child did not thrive. The stools were never colourless till about a week before death. The child lived till the eighth month, and then died after a few days of broncho-pneumonia, having shown slight oedema of the feet and hands during this last illness. From peculiar circumstances, only the liver was examined. It was much enlarged, had sharp edges, and was almost cartilaginous in hardness. The peritoneum covering it was adherent. The surface was dry, dull, and granular from prominent greyish-green elevations, about the size of pin's heads. On section the parenchyma was green, the vessels appeared as yellowish-grey cords of almost cicatricial hardness; and dark green bile flowed freely on section. All the biliary passages were narrower than normal. The common bile-duct was pervious, but very narrow. Only the right hepatic duct could be followed for any distance into the liver. The left hepatic duct was obliterated very soon after it entered the liver, its place being taken by strings or cords of greyish connective tissue which accompanied the portal vessels. The cystic duct was entirely absent. The gall-bladder was in its normal situation, but had become adherent to the under surface of the liver by very firm fine connective tissue. It was flaccid, only partially filled, was of whitish-grey colour, and contained clear, thin faintly acid mucus. On laying the gall-bladder open no outlet was discoverable. The cystic duct was replaced by solid thin whitish strings, which were interspersed with some soft, round, solid dark green bodies (apparently lymphatic glands). The blood-vessels of the liver appeared normal. The ligamentum teres admitted a stout probe as far as the portal vein. The ductus venosus was imperfectly

closed. Microscopic examination showed the liver changes to be cirrhotic. Dr. Lotze considers this to be a case of intrauterine perihepatitis—possibly due to congenital syphilis (although this seemed very problematic, the father's history only revealing an ulcer of doubtful character three years before). This had probably prevented the proper development of the bile-ducts.

W. BATHURST WOODMAN.

SANGALLI ON THE CONDITIONS OBSERVED IN THREE CASES OF ABSENCE OF KIDNEY.—In 5,348 necropsies Professor Sangalli (*Rendiconto del Reale Istituto Lombardo*, vol. ix. and *Lo Sperimentale*, August, 1876) met with the following anomalies in the kidneys.

Displacement of one kidney, seven cases; Displacement and union of both kidneys, one; Displacement of the left kidney with excessive development of the suprarenal capsule, which, remaining in its proper position, suggested the idea of a double kidney on the left side, one; Simple union of the kidneys at the lower part, three; Union of the two kidneys with abnormal division of the renal substance, so as to give the appearance of five kidneys each provided with its own pelvis (the five pelvises being found reducible to two), one; Double ureter on one side, the other being normal, one; Double ureter on both sides, one; Congenital atrophy of one kidney in an adult in whom the toes were absent.

Of the seven cases of unilateral ectopia, four were on the right side and three on the left. The displaced kidney lay either on the last lumbar vertebrae, or on the promontory of sacrum, in the small pelvis. In none of the cases had there been any complaint of inconvenience; in one, however, there was an excessively developed suprarenal capsule on the same side. Dr. Sangalli observes that these cases of displaced kidney are of importance with reference to the diagnosis of enlarged spleen. As regarded sex, the numbers were nearly equal.

Absence of the kidney was found in three cases, all males, among the 5,348. All the individuals were otherwise well formed and had been of ordinarily robust constitution. They died of diseases having no relation to the anomaly of the kidneys; one (aged twenty-five) of metastatic (pyæmic) abscess of the liver after a wound of the head; another (aged forty-nine) of rheumatic pleuro-pneumonia and consecutive meningitis; the third (aged forty-six) of phlegmonous erysipelas of the right hip, with metastatic peritonitis and pleurisy, and albuminous nephritis. In one case the right kidney was wanting; in two, the left. In the first case, the remaining kidney appeared to be simply hypertrophied to twice the natural size, and in the second, it was increased through hypertrophy by about one-third, and was affected with incipient albuminous nephritis; in the third, the kidney was enlarged by about one-half by hypertrophy and by chronic albuminous nephritis. In each of the cases, the kidney occupied the usual position, and the ureter was normal.

The suprarenal capsule was present in its normal position on both sides in each of the three cases; in one case it was larger on the side where the kidney was absent than on the other.

In addition to the absence of the kidney—of which no trace could be found in these three cases—the vesicula seminalis and ejaculatory duct on the same side were wanting, although both testes were perfect.

* Dr. Lotze gives the following references:—Virchow's *Archiv*, Bd. 35, p. 360; Binz, 'Zur Kenntniss des tödtlich Icterus der Neugeborenen aus Obliteration der Gallenwege,' *Ibid.*, Bd. 43, p. 296. Roth, 'Congenitaler Defect der grossen Gallengänge,' *Archiv der Heilkunde*, Bd. 11, 1874; Schüppel, 'Ueber Perityphlitis bei Neugeborenen,' quoted in Gerhardt, *Kinderkrankheiten*, 3 Aufl. *Transactions of the Pathological Society*, vol. xxxiii., p. 152; Nunneley, 'Congenital Obliteration of the Hepatic Ducts.'

This anomaly, Dr. Sangalli says, has not been described by others. On endeavouring to ascertain what became of the semen secreted on the side where the defect existed, Dr. Sangalli found in one of these cases that, on the side where the kidney was present, the vas deferens was normal in size and course; but at the other (left) side it was slender, and, after entering the pelvis beneath the fundus of the bladder, passed obliquely to join the right spermatic vesicle, into the vas deferens of which it opened about a centimètre from the point of entrance of the right ureter into the bladder.

PIPPINGSKÖLD ON SUBPUBIC EXTROPHY OF THE BLADDER IN A GIRL.—The case is described by J. Pippingsköld (*Finska läkaresällskap. förhandling.* Band xvii.; and *Nordiskt Medicin. Arkiv*, Band viii.) A girl aged thirteen, who had not yet menstruated, suffered from nocturnal enuresis, and in the day time could not retain her urine for more than an hour and a-half at a time; it hence was frequently discharged in a rapid stream. On examination, the anterior wall of the abdomen was found to be normal, and the symphysis pubis closed, of normal height, but broader than usual. In the situation of the mons Veneris was a vertical cleft two centimètres wide and one deep, which led downwards and backwards into an opening more than a centimètre wide, in which the mucous membrane of the bladder was visible. The opening was bounded on the two sides by the nearly parallel halves of the clitoris. Of the urethra, there was only a short rudiment of the posterior wall; the whole anterior wall was wanting. The glans clitoridis lay one-and-a-half centimètres above the urethro-vaginal septum; the labia majora were fully developed, the fossa navicularis was absent. Two separate operations were performed without result.

PIPPINGSKÖLD ON CONGENITAL STENOSIS OF THE COLON AND ILEUM.—In a new-born child, which at the end of the first twenty-four hours was attacked with vomiting, which continued until its death on the seventh day after birth, J. Pippingsköld (*Finska läkaresällsk. förhand.* Band xvii., and *Nordiskt Medicin. Arkiv*, Band viii.) found the following appearances. The rectum was fully formed as regarded both length and width; but the colon for about fifteen inches was no thicker than a large goose-quill, and contained no meconium. The cæcum, which was somewhat larger, was empty: the vermiform appendix was five centimètres (two inches) long. The lower part of the ileum for about two inches from the cæcum was of the size of a small goose-quill. Beyond this, there was apparently a complete defect of intestine; but, on searching along the free edge of the mesentery, there was found a rudimentary bowel from one to two millimètres in thickness; it had no evident lumen, but passed into an enormously distended small intestine.

TIBALDI ON JAUNDICE FROM ATRESIA OF THE BILE-DUCT THROUGH CIRRHOSIS OF THE HEAD OF THE PANCREAS.—In the *Annali Universali di Medicina e Chirurgia* for June, 1876, Dr. Tibaldi describes a case of a married woman, aged thirty-five, who had enjoyed good health up to two months before she was first seen. She had gradually become jaundiced, and had some oppression and pain in the epigastrium and right hypochondrium, with much loss of appetite; she occasionally had slight fever. On examination Dr. Tibaldi found the liver enlarged

and resistant; the gall-bladder distended, and reaching as far as the umbilicus; the spleen enlarged and resistant, and extending as far as the left iliac region; tympanitic abdomen; regular discharge of colourless pieces; urine scanty, of a yellow-green colour; the skin yellow and itching; the impulse and sounds of the heart indistinct; the pulse weak and slow, intermitting at every tenth beat. There was plainly icterus form, suppression of the flow of bile. At the necropsy the head of the pancreas was found enlarged to double its normal size, with a mass of puriform matter in its centre, and the bile-duct was atrophied for some distance from its point of entrance into the duodenum. Dr. Achilles Visconti found, on histological examination, hyperplasia of the interstitial connective tissue, with pyoid globules and cells of cylindrical epithelium in the pancreatic duct mixed with mucus, without any trace of cancerous formation. A. HENRY, M.D.

MEDICINE.

MARTEN ON TWO NEW SYMPTOMS OF ADHESIONS OF THE PLEURÆ.—Dr. Marten, of Hörde, writes as follows in no. 30 of the *Berliner Klinische Wochenschrift*, July 24, 1876. 'On March 27, 1875, I was suddenly taken ill, having previously had no other symptoms of illness, except that some weeks before the pulse had been intermittent. There was, however, no organic disease of the heart, and I had continued my professional work. Now, however, I was suddenly seized with most acute pleuro-pneumonia of the left side. The whole of the left lung became quickly hepatized. There was, however, no great amount of pleuritic exudation. After five days, the crisis occurred, the treatment being wine, with morphia at night, partly on account of a distressing and convulsive cough, which gave me no rest at night unless I took the opiate. The next trouble was an alarming amount of meteorism, by which the diaphragm was pushed up beyond the line of the nipples. By the use of purgatives, this subsided in a few days. The upper lobe of the right lung was attacked on April 10, but fortunately the symptoms vanished in twenty-four hours. From this time forward, convalescence, though tedious, was unin-

interrupted, and six weeks' Alpine air rendered me fit for my work again, the only subjective symptom of my illness being a little unusual excitability, and the only objective one some slight thickening of the pleura at the left base. There were, however, two symptoms, which I consider worth recording, as they do not appear to have been previously noticed. They were, however, quite obvious to my medical attendants, and those around me, as well as to myself. They can also be easily explained. After lasting three months, they are now gradually disappearing. When the volume of the stomach underwent any change, as just before, during, and after a meal, there were frequently repeated, spasmodic, and rather painful, contractions of the upper part of the gullet and pharynx, a sort of wind-swallowing (*blindesschlucken*), which would last for some seconds, rendering both eating and speaking impossible. Not only did I feel these, but others could clearly see them. No doubt the mechanism was, that any sudden change in the size of the stomach, the diaphragm perhaps assisting, perhaps being only passive, caused the adhesions of the pleura to the œsophagus to be put on the stretch; thus setting up the contractions of the upper part of the alimentary tube which I felt and others saw.

'It is well known that recent inflammatory adhesions of the pleurae to the lung, give rise, for a long time after, to pain in sneezing and coughing, these acts putting them on the stretch. The bystanders will notice that the patient presses his hand against the corresponding ribs.

'The second symptom, though less easy to explain, was still more manifest than the spastic contractions of the constrictor muscles of the pharynx mentioned above. This symptom was as follows. If breathing had become superficial or shallow for a short time, through the body and mind being both at rest, which most commonly happened in bed, before going to sleep, a noisy deep inspiration suddenly took place, with a jerk, which could be seen, felt, and heard, and this kind of thing went on at intervals of a few minutes several times before sleeping. It never occurred in the mornings; always under the circumstances described, and always on the left side. It might be called a one-sided yawn, and might probably be due to the same cause: only, as the pretty extensive adhesions of the pleura on the left side caused less perfect expansion of the left thorax, this was probably compensated by a sudden and irresistible contraction of the diaphragm, which was assisted by a more powerful, visible, and audible expansion of the left hypochondrium.'

[The reporter thinks it possible the pneumonia had a good deal to do with the last symptom, which seems only an exaggeration of the action induced by the stimulus of what M. Bourdon in his '*Recherches sur le Mécanisme de la Respiration*,' calls by the appropriate name of the '*besoin de respirer*.' In relation to this partial suspension, Dr. Carpenter says: 'If, however, we endeavour to prolong the suspension, the stimulus conveyed by the excitator nerves to the medulla oblongata becomes too strong, and we cannot avoid making inspiratory efforts; and if the suspension be still further prolonged the whole body becomes agitated by movements which are almost of a convulsive nature, and no effort of the will can then prevent the ingress of air.' ('*Principles of Human Physiology*,' 7th ed. p. 329; see also his remarks on breathing in sleep, and on sighing.) However, be the interpretation as it may, these

observations, if less novel than Dr. Marten thinks, are of great interest, particularly on account of the length of time during which they persisted.—*Ref.*]

WEISS ON THE OPERATIVE TREATMENT AND RAPID RECOVERY OF A CASE OF EMPYEMA DISCHARGING ITSELF THROUGH THE LUNG.—Staff-Surgeon Dr. Weiss reports the following case in *Betz's Memorabilien*, xxi. Jahrgang, Heft 6, s. 261. C. V., twenty-one years of age, weighed 124 pounds on November 3rd last. The circumference of his chest was 36 to 37½ inches, and his lungs had a vital capacity of 213 cubic inches. On January 25 of this year, he was attacked with pleuro-pneumonia of the left side. The symptoms of pulmonary inflammation subsided, along with a fall of temperature; and on February 4, the latter was 101·66° Fahr. The pyrexia did not, however, entirely leave him, and on February 7, the thermometer marked 102·92° Fahr., whilst simultaneously the pleuritic symptoms, which had previously played a subordinate part, began to attract attention. The rise of temperature continued in spite of antipyretic treatment, so that his evening temperature averaged 102·74° Fahr.; and on the 28th instant amounted to 104° Fahr. On this day, the patient, whose sputa, since the subsidence of the pneumonia had consisted of frothy mucus, discharged a great quality of creamy, yellow, odourless pus—filling five common drinking glasses. This was accompanied with a most tormenting cough, and attacks which seemed to threaten him with suffocation. Dr. Weiss did not see him either on this or the two next days. On March 2, he brought up three more tumblers of similar fluid in the forenoon, and appeared extremely weak and exhausted. As there could be but little doubt that the diagnosis must be 'discharge of an empyema through the lung,' as moreover the cough threatened complete exhaustion, and as the prognosis of such cases, when left to nature, is seldom favourable, Dr. Weiss, on March 3, did paracentesis thoracis by Lister's (antiseptic) method, in the left axillary line between the seventh and eighth ribs; making a free incision, and afterwards washing out the cavity with a solution of salicylic acid. Nearly sixteen ounces of pus were thus removed. One of Kussmaul's catheters was connected with an irrigator, in order to do the washing out. The patient was momentarily much distressed, the cough and dyspnoea being greatly increased at first. The sputa tasted of salicylic acid. Jute impregnated with the same acid was used as a compress. As soon as this bandage was applied, all the symptoms of irritation ceased, and the patient enjoyed a degree of rest to which he had been a stranger for some days. The chest was washed out with the same fluid, at first daily, then every other day, till the quantity of pus became so small that it could be conveniently coughed up. This washing out always excited cough and distress, which, however, very quickly subsided. On April 2 the wound was quite healed, and from this time the sputa became daily less purulent and more mucous, till they ceased eight days after the healing of the wound. From this date he might be considered as convalescent. On May 6, he was found to weigh 128 pounds; the circumference of his chest was 36½ to 37½ inches; and the vital capacity of his lungs was found to be 171 inches. This diminished vital capacity (it had been 213 cubic inches before) was partly explained by slight emphysema of the right lung, and partly by the still imperfect expansion of the left lung.

JACOBS ON RECOVERY FROM EMPYEMA AFTER SPONTANEOUS EXTERNAL OPENING (*Paracentesis per Necessitatem* of old writers).—Dr. Jacobs, of Cologne, reports the following in the *Deutsche Medicinische Wochenschrift* for August 5, 1876. M. K., aged twenty-three, a consumptive-looking girl, was suddenly attacked with inflammation of the lungs, accompanied with suppression of the catamenia. Her pneumonia apparently terminated in suppuration. The treatment pursued was very varied, as she had several doctors. Dr. Jacobs first saw her in the sixth week of her illness. She was much emaciated, had very offensive purulent sputa, and suffered from fever with morning remissions. The exacerbations or febrile paroxysms were sometimes in the afternoon, sometimes at night. Her average temperatures were about 38°·2 Cent. in the morning, 38°·5 Cent. in the afternoon, and 39° or 40° Cent. in the evening (or 100°·6, 101°·3, and 102°·2 to 104° Fahr.). Her pulse was never less than 100, and often rose to 140 at night. There were repeated rigors. The afternoon and evening elevations of temperature were generally followed by perspirations. She complained of want of appetite, shortness of breath, weakness, and sleeplessness. Mucous râles could be heard on the right side by the unassisted ear. On the right side, from the third to the sixth rib in the anterior axillary line, there was dulness on percussion, and auscultation revealed mucous râles, metallic tinkling, and pectoriloquy. The mucous râles were too loud to permit any vesicular breathing to be heard at this spot. Dr. Jacobs diagnosed a vomica and empyema as a consequence of caseous pneumonia. The course of the disease indicated pleuro-pneumonia (there had been rusty sputa). The constitution, prominent clavicles, and the shape of the thorax all rendered tubercle probable. Quinine in large and small doses seemed to have no particular effect on either temperature or pulse. Morphine and chloral-hydrate by mouth and subcutaneously relieved her cough, and procured more tranquil nights. Her increasing fever, loss of strength, want of appetite, increasing pulmonary mischief, and aggravated dyspnoea, all appeared to indicate death from exhaustion to be imminent, when she called attention to a slight swelling between the fourth and fifth ribs on the right side in the axillary line. It had the form and about the size of a walnut, was brownish red, soft, and tender on pressure. Oiled linseed poultices were ordered as it was intended to open the swelling next day. Being unable to visit her for two days, Dr. Jacobs found on the third day that the 'abscess' had broken, discharging a large quantity of thin, whitish, bad smelling pus. From this time the cough, expectoration, and fever gradually decreased. The treatment was chiefly tonic, with local use of poultices, drainage-tubes, etc.; and in three months the opening was closed. The patient recovered; and although it is two years ago, has not relapsed. Her case thus contrasts favourably with that of Dr. Von Nelsen, aged about fifty, also treated by Dr. Jacobs. In his case there appeared to be a communication between an empyema due to pleuro-pneumonia, and one of the large bronchi (as in the case reported by Dr. Weiss in Betz's *Memorabilien*, xxi. Jahrgang, Heft 6). Great dyspnoea and much cyanosis led Dr. Jacobs to do thoracocentesis, and an immense quantity of whitish stinking pus escaped. The opening closed after two months; but in four weeks' time it broke open again, and a probe revealed caries

of the fifth and sixth ribs. This fistula remained open, and the patient died of phthisis in about six months. Dr. Jacobs, in commenting on these cases, remarks on the comparative safety of puncture by the aspirator. Yet he thinks that in some cases, a free opening with the knife, such as Ewald recommends in the new *Charité Annalen*, is equally safe, and more desirable for some reasons. A review of Ewald's cases will be found in nos. 6 and 7 of the *Deutsche Medicinische Wochenschrift* for this year. [See also LONDON MEDICAL RECORD for July, page 324.] W. BATHURST WOODMAN.

MILES ON A CASE OF CEREBRAL HÆMORRHAGE AND HEMIPLEGIA.—At a meeting of the American Neurological Society (*New York Medical Record*, July 15), Dr. F. T. Miles of Baltimore related a case which was interesting, from the fact that the injury of the brain in a particular locality was connected with the exact symptoms observed before the death of the patient. The brain-injury in this instance occurred in an eminent lawyer who, at the time the symptoms were first developed, was cross-examining a witness. A fac-simile of his handwriting was exhibited, and it could be seen exactly where irregularities in the outline of the letters began to show themselves. From that point the chirography grew more and more illegible, until finally a mere blot was made. The gentleman then rising to address the court, it was perceived that something was wrong with him, and he was removed from the room. He became semi-comatose, had complete right hemiplegia, the right side of the face was completely paralysed, and ptosis of the left eye was strongly marked. The tongue was not paralysed, but the patient was unable to thrust it out, and there was no paralysis of the muscles of deglutition. There was some anæsthesia upon the affected side. The patient answered all questions affirmatively. The eyes could be made to follow the finger only as far as the median line to the right, when they would stop, and the patient would carry them over to the left side. The case terminated in the usual deep coma and death. Dr. Miles had diagnosticated crural hæmorrhage, producing ptosis, with paralysis upon the opposite side. At the necropsy, a mass of blood which had so flattened the convolutions, that it could be easily seen beneath the surface, was found in the central portion of the middle lobe of the brain upon the left side. When the sac was opened, the first blood that escaped was fluid; then came a jelly-like mass; and, lastly, a hard clot, not easily broken up, which was probably the original clot that gave rise to the first symptoms. The clot did not break through into the ventricles, but remained enclosed in the substance of the third lobe. Dr. Miles referred to a case in which an abscess was found in the region occupied by the original clot in the case being described, but in which there was no motor paralysis. In the present instance, the necropsy proved that the diagnosis was incorrect, because there was no hæmorrhage into the crus. The symptoms, therefore, were explained by the double influence produced by the destruction of brain-substance, and pressure upon the surrounding parts; and that it was the pressure upon the crus and the third nerve that gave rise to the eye-symptoms.—Dr. Jewell remarked that the fact of the symptoms in Dr. Miles's case being due to pressure produced upon parts outside of the real lesion, showed how easily mistakes could be made with reference to diagnosis and pro-

gnosis.—Dr. Hammond inquired with reference to dilatation of the pupil and strabismus.—Dr. Miles replied that there was no special dilatation of the pupils, and that he did not observe any strabismus.—Dr. Hammond, from those facts, was inclined to regard the ptosis as entirely independent of intracranial trouble. He did not regard the case as one of cross-paralysis, but that the ptosis depended upon some orbital lesion.—Dr. Seguin directed attention to one symptom in Dr. Miles's case which would cast a doubt upon the diagnosis of affection of the crus—namely, the eye symptom. The fact that the patient could not be induced to turn the eye beyond the median line to the right, and tended to look to the left, was in obedience to what occurs in lesions of the hemispheres and not in lesions of the crus. From that fact alone he would have been led to believe that the lesion was not limited to the crus.

STREETS ON A CASE OF NATURAL CATALEPSY.—In the *American Journal of the Medical Sciences* for July, Dr. T. H. Streets narrates a case of catalepsy, which came under his notice in a sailor, named Thomas Lakin, in the American navy. Previous to shipping in the government service, the man, who had been healthy, had been employed on a steam-boat on the bay of San Francisco. While there, a boiler explosion took place, and the boat was blown in pieces. He stated that he received no injury at all from the accident, that he was not struck by any of the flying missiles, nor scalded by the steam, but that he was projected into the water by the force of the explosion.

Some time after this occurrence (probably somewhat less than two months), he began to experience a prickling sensation in the region of the occiput. After his enlistment in the service of the government, more than a year after the date of the explosion, he became subject to fits of unconsciousness. The first attack occurred while he was away from the ship, and while he was on duty in a small boat taking soundings. It was the patient's duty to heave the lead. The officer on duty noticed that he was neglecting his business, and spoke to him in consequence, but received no response. He was in the attitude which he had assumed in the act of heaving the lead—the left foot planted in advance, the body leaning slightly forward, the right arm extended, and the line held in the left hand. The fingers were partially flexed, and the sounding line was paying out through them in this half-closed condition. The eyes were moving about in a kind of wandering gaze, as in one lost in thought. So much like his natural self did he appear, that his officer again spoke to him, and this time rather harshly, under the impression that he was disregarding his orders intentionally. He remained standing in this posture for two or three minutes, and maintained his equilibrium, and the boat was in no wise perfectly steady at the time. The whole duration of the trance was about five minutes.

After this he had a number of attacks, but none of them were longer in duration than the first; sometimes they lasted no longer than one or two minutes. Most of them occurred while he was away from the ship. They did not incapacitate him for duty, but some apprehension was felt lest he should fall overboard, and for this reason he was closely watched.

The only premonition he ever had of the approach of an attack was a sense of suffocation, or an inability to breathe. This did not always precede an

attack; he experienced the sensation but once just before lapsing into unconsciousness; generally they came on without any warning whatever. Once he felt sick at the stomach immediately after he recovered consciousness, but, as a rule, they left him as well as they found him, and he would take up his work just where he had left off, as if nothing at all had happened. No symptoms of nervous derangement were noticeable in the case. As the disease progressed, they assumed more and more an epileptic character, and before he passed out of Dr. Streets' care entirely, the catalepsy had become converted into well-marked epilepsy.

The patient had been granted forty-eight hours liberty on shore, and during that time he had partaken rather freely of alcoholic liquors, but he was not drunk. He reported himself on board the ship promptly at the expiration of his leave of absence, and he had been aboard but a very short while when Dr. Streets was called upon to see him in a fit. The loss of consciousness in this instance was accompanied by a complete loss of muscular control, and he had fallen to the deck. The face had a livid, cyanosed appearance, and the eyes were fixed and staring, but there were no convulsive movements of the muscles, nor foaming at the mouth. The manner of recovery was also similar to that observed in the cases of 'petit mal' of the French; he presented the same dazed, confused appearance, like one who has been suddenly awakened from a sound sleep. This attack occurred about six months after the manifestation of the first morbid symptoms. There was no history of epilepsy in his family that Dr. Streets could learn.

At this stage the case passed out of Dr. Streets' care and sight entirely, in consequence of his being ordered to duty elsewhere.

Bromide of potassium in twenty-grain doses, given twice daily at first, and afterwards reduced to once daily, given at night, controlled the paroxysms completely, but directly this medicine was discontinued they would recur.

DÉJÉRINE AND GOETZ ON ACUTE ASCENDING PARALYSIS.—MM. Déjérine and Goetz (*Archives de Physiologie*, May, June, 1876), report a case of this disease which was originally described by Landry as acute ascending paralysis without lesion of the cord. Their case was that of a man, otherwise in good health, who was admitted into the hospital for vague pains in the lower limbs; two days after admission he became paralysed in his lower limbs; the paralysis progressed rapidly, and he died in less than four days of asphyxia. The lungs were found to be congested, but the other thoracic and abdominal organs seemed perfectly healthy. The brain showed no trace of alterations to the naked eye. The spinal cord appeared healthy; it was hardened and carefully examined microscopically in its whole length; the vessels were dilated, but no lesion was found in the cells, nerve-tubes, or neuroglia; the roots were not examined in the fresh state, but some pieces of an anterior cervical root were examined after hardening, and an atrophy of some of the tubules with an increase of the nuclei of the intertubular connective tissue was noted. Similar cases, in which no lesion of the cord could be demonstrated, have been recorded by Vulpian, Chalvet, Pellegrino Levi, and Hayem. This disease differs clinically from acute myelitis in complete persistence of sensibility, and the absence of trophic changes in the paralysed parts. The

authors regret that the examination of the nerve-roots was not made; they suggest that either this disease is some inappreciable physico-chemical change in the nerve-elements, or its seat is possibly in the nerve-roots, which latter hypothesis has the support of the changes noted above in the single nerve-root examined in this case.

BERNHARDT ON ATHETOSIS.—Dr. Martin Bernhardt (*Virchow's Archiv*, May, 1876), has a paper on this disease, which has only been recognised for the last five or six years, since Hammond described it. He says it consists of involuntary movements, strangely restricted to the fingers and toes, not disordered as in chorea or trembling as in paralysis agitans or disseminated sclerosis, going on during sleep, accompanied by diminution of the cutaneous common sensibility, followed by hypertrophy in the groups of muscles concerned in the movements, and for which hitherto all therapeutic means have been useless. He cites cases published by Hammond (6), Clifford Allbutt (1), Currie Ritchie (1), and Gairdner (1). His own case was that of a boy aged twelve, born of healthy parents, who had suffered from this affection since the age of four, when he had a severe illness, which appeared to have been some exanthema. One of his brothers had died of chorea, and a sister had suffered also from chorea, but had recovered. The boy's intelligence and general health were good, and in short, nothing was observable but a slight loss of power of the right side; the tongue on protrusion inclined slightly to the right side; the pupils were equal; he suffered often from headache. He could stand well on both legs, and walked well. When his attention was not directed to his right hand, the little finger, index finger, and thumb commenced their movements by abducting, adducting, flexing and extending themselves in a remarkable manner. Also when walking, the foot was sometimes drawn up into the varo-equinus position, the toes being drawn down towards the floor. The muscles of the right forearm were hypertrophied, although owing to his condition he had learnt to write and serve himself with his left hand. The movements continued in bed. The other functions were healthy. He remained under treatment some months without change. Dr. Bernhardt proceeds, after relating this case, to inquire whether we are justified in considering that we have to do with a group of symptoms deserving to be considered as a distinct disease. He points out that its range as to age, its extraordinary restriction to the most peripheral parts of the limbs, the nature of the movements, and its one-sidedness, distinguish it from paralysis agitans and disseminated sclerosis. He thinks that it more nearly resembles a hemichorea. The cases on record give several instances of its occurrence in persons who have suffered from some brain-affection, as epilepsy or apoplexy; and he considers it to have analogies with the group of diseases called by Dr. Weir Mitchell postparalytic chorea, or by Charcot, *hémichorée post-hémiplégique*. In this last affection, M. Charcot localises the lesion behind the optic thalamus and nucleus caudatus, in the most posterior part of the foot of the corona radiata in the hemisphere opposed to the limbs affected. In the absence of any dissections, Dr. Bernhardt admits the impossibility of localising the lesion in athetosis; but, taking all the facts into consideration, he is disposed to imagine it as occurring in the hinder part of the internal capsule.

ROBERT SAUNDY, M.B.

SERGEANT ON THE SYMPTOMS OF ENTERIC FEVER FROM DRINKING CONTAMINATED MILK.—Mr. Edward Sergeant, of Bolton, writes as follows in the *Medical Times and Gazette* for August 26, respecting the symptoms observed in patients affected by drinking contaminated milk from a farm at Eagley in the early part of this year.

In investigating the epidemic of enteric fever which caused so much havoc in Bolton and the neighbouring village of Eagley, one was struck by the suddenness of the outbreak, by the constant prevalence of certain marked symptoms, and by the direct connection of attack with the drinking of milk supposed to be contaminated. By far the larger majority of the patients dated their illness from the week ending Feb. 6. Before this several isolated cases had occurred, and afterwards there was a gradual diminishing of cases until Feb. 23, when the epidemic appears to have ceased. The commencement of the attack was in almost all cases the same; the symptoms being rigors, pain in the head (in more than one instance so intense as to have led the medical attendant to suspect meningitis), pain in the back and limbs, and abdominal pains, usually very severe. The bowels were at first constipated; the tongue was coated with numerous papillæ, projecting as red points. Fever, as shown by the pulse and rise of temperature, was always present. In some cases, after two or three days' suffering, intense delirium came on, followed not unfrequently by coma. Vomiting, occasionally directly after drinking the milk, was another marked feature at the commencement of attack. In a few patients evidence of gastric irritation, with the above-mentioned symptoms, more or less severe, composed the entire disease; in others recovery did not take place until the patient had passed through a disease marked with all the symptoms characteristic of enteric fever. The temperature increased, with remissions night and morning; the tongue became dry and covered with sordes; the urine heightened in colour, and had a higher specific gravity; the abdomen enlarged, and became resonant, with greater sensitiveness on pressure, especially in the right iliac region; diarrhœa came on; and in some of the worst cases the acute febrile condition was succeeded by great prostration, with low muttering delirium and subsultus tendinum. The eruption of rose-coloured spots, characteristic of typhoid fever, was present in only a small proportion of the cases, but when noticed it was very copious, mostly covering the abdomen, thorax, and thighs. Hæmorrhage from the bowels or nose was very exceptional; in only one or two cases was this observed. Pulmonary complication was not at all uncommon; in two patients the mischief was so great as to be the immediate cause of death. Relapses were of frequent occurrence; one patient who, at first, apparently had a mild form of the disease, died after a third relapse with suspected perforation of the intestines. Recovery was the most frequent termination of the disease. Out of 111 patients whose illness was clearly traceable to the infected milk, only six proved fatal, namely, two males and four females, of the ages of fifteen, eleven, seventeen, eighteen, fifty, and thirty-four years respectively. As is usual in cases of enteric fever, the period of convalescence varied; in some the disease was gone through in from ten to fourteen days, while in others convalescence was delayed for weeks, the patient being troubled with some of the sequelæ which so often retard the recovery of typhoid patients. The

average duration of illness at all ages was 30·3 days. This varied somewhat according to the age of the patient—for instance, under five years of age the average duration of illness was 29·8 days; between five years and twenty years, 32·5 days; and at twenty years and upwards, 30·3 days. Of the 111 patients attacked, 46 were males and 65 females. The ages were as follows :

Under 5 years	.	.	.	15
Between 5 years and 10 years	.	.	.	14
" 10 "	.	.	.	11
" 15 "	.	.	.	29
" 25 "	.	.	.	19
" 35 "	.	.	.	12
" 45 "	.	.	.	8
" 55 years and upwards	.	.	.	3

As is usual with such epidemics, the largest proportion of cases took place below twenty-five years of age, and these were made up principally of women and children. The decreased susceptibility with advance of years was also observable.

The following are brief notes of a *post mortem* examination made on March 7, on the body of a patient, aged eleven years, who died three days previous, having suffered from the effects of the milk poisoning fifteen days: Body emaciated; great *post mortem* discolouration, extending along the sides of the chest; bed-sores commencing over sacrum; teeth and gums covered with a black coating; abdomen contained a small quantity of fluid; intestines distended with flatus; mesenteric glands swollen and vascular (some of the glands near the ileo-cæcal valve were especially enlarged and congested). About a foot from the commencement of the ileum, separated by a few inches, I found two Peyer's patches, each measuring about one inch long by half an inch wide; they were considerably indurated, and elevated about a line above the surrounding intestines. One of the patches had a portion about the size of a split-pea rather more raised than the rest, and covered with a black slough. In close proximity to these there were three other portions of indurated gland-tissue; one, about the size of a horse-bean, was surrounded by an inflamed areola, and in a state of slough. Kidneys congested, apparently undergoing fatty degeneration. Spleen enlarged, of a blackish red colour and pulpy. Lungs: Both bases were in a state of red hepatisation; the right base on being cut showed a muco-purulent infiltration; proceeding to the upper lobe of both lungs the congestion faded into healthy lung-tissue. Liver enlarged and congested. Heart contained no blood; healthy. The other organs presented a healthy appearance.

SURGERY.

FISCHER ON THE ADMINISTRATION OF CARBOLIC ACID TO DIABETIC SUBJECTS BEFORE SURGICAL OPERATIONS.—Dr. H. Fischer, of Breslau, states in the *Deutsche Medicinische Wochenschrift*, no. 14, 1876, that in Germany the number of diabetic patients is very much on the increase. This fact he attributes to the mental excitement due to extreme and sudden political changes, and to rapid alternations in social position. The author holds with Seegen that diabetes is an affection of the nerves, commencing in nerve-lesion, and terminating in psychical disturbance. He has also been struck with the frequent association of diabetes with cardiac disease, particularly with that form in which the muscular tissue of the heart is affected, together with the valvular apparatus. It often occurs that surgical affections, such, for instance, as tumours, necrosis, and caries of bone, etc., met with in diabetic patients, are of such a nature as to render surgical operation necessary or desirable. The use of the knife, however, in such cases is very dangerous, as, according to general surgical experience, the smallest wound in a diabetic patient is usually followed by severe, extensive, and frequently fatal gangrenous inflammation of the subcutaneous cellular tissue. Such inflammation, indeed, is often developed without traumatic cause in the subjects of advanced or overlooked diabetes. When an operation is urgently demanded, as in case of rapid growth and breaking down of a tumour, it becomes the duty of the surgeon to apply, if possible, some treatment that may improve the condition of his patient, and favour the chances of a successful result from his operation.

The author, with this object in view, has lately carried out the carbolic acid treatment recommended by Ebstein and Müller; and he reports that, if this agent be administered internally in small and frequently repeated doses, it will in a short time cause a considerable reduction in the amount of sugar in the urine, and permit the surgeon to perform his operation with the ordinary chances of success. The use of carbolic acid should, it is stated be kept up during the after-treatment, and not be discontinued until the wound formed in the operation be quite closed. In cases of severe and extensive inflammation following an important operation in a subject of overlooked diabetes, the author has frequently succeeded in arresting the local mischief by reducing the amount of sugar in the urine through the administration of carbolic acid. He has also observed good results from an energetic administration of carbolic acid in cases of the so-called diabetic carbuncle. In this affection, however, the treatment often fails, in consequence of the rapid prostration of the patient, of the great extent and intensity of the inflammation, and of early septic infection.

RANKE ON POSTERIOR CATHETERISM.—Dr. Hans Ranke of Halle has recently published a continuation of his experience of this operation (*Deutsche Medicinische Wochenschrift*, no. 29, 1876). In a former number of the same periodical, (no. 6, 1876), this author reported a case from Volkmann's clinic, in which posterior catheterism, that is to say, catheterism of the urethra from the bladder, had been performed with excellent results. He then believed that the operation was indicated in cases in which it was not possible in external urethrotomy for impermeable stricture to divide successfully the whole of the strictured portion of urethra, and to find the proximal extremity of the stricture. A recent case has convinced the author that the associated practice of posterior catheterism can render the otherwise very difficult operation of external urethrotomy one of the easiest of surgical proceedings. The subject of this case was a workman aged fifty-one, who had traumatic stricture of nineteen years standing. In January of the present year he suffered from complete retention, and, as the stricture was found by his medical attendant to be impermeable, the bladder was relieved through suprapubic puncture. The patient came under the author's observation on March 8; he was then a strong and fairly nourished man, but slightly anæmic. On perineal examination; there could be felt a firm material mass in the region of the bulbous portion, which had fixed the urethra to the limbs of the pubic arch. Just above the symphysis was a small granulating punctured wound, occupied by a thick catheter through which was discharged alkaline and turbid urine. This was certainly a case that could be permanently relieved only by external urethrotomy; but it was clear that the operation would be attended with great difficulty, as no guiding instrument could be passed through the stricture. This, then, was thought a good opportunity for testing the value under such circumstances of posterior catheterism. The first attempt made to pass a catheter through the suprapubic punctured wound and the bladder into the urethra failed, as the catheter used was too small and too elastic. This was replaced by a larger and firmer instrument, which at the first trial was passed through the vesical orifice of the urethra.

The beak of the instrument was then readily passed down to the posterior extremity of the stricture, and could be felt on perineal examination in the membranous portion of the urethra. A second catheter having been passed by the penis as far as the anterior extremity of the stricture, there was found to be an interval of about an inch in extent between the extremity of this instrument and the extremity of the instrument passed by the bladder, which interval corresponded to the contracted portion of the urethra. The proceeding of posterior catheterism was then repeated several times without any difficulty. On the following day two catheters were again introduced, one through the suprapubic wound and the bladder, the other by the penis, and the callous portion of urethra between the ends of the two instruments incised. The bleeding from the cicatricial tissue causing the stricture was very slight. An attempt was now made to follow the urethra from before backwards through the stricture, but without success. Then the end of the catheter introduced by the bladder, which could be distinctly felt just in front of the prostate, was laid bare, the proximal extremity of the strictured portion of urethra opened, and finally the remaining callous portion slit up. It was found that the proximal extremity of the stricture had been displaced, through cicatricial retraction, to the left side of the median line. The whole operation from the first incision of the skin occupied but a few minutes. A silver catheter (no. 12) was passed through the stricture and retained in the urethra, and through this instrument a weak solution of hydrochloric acid was passed twice daily into the bladder. The subsequent progress of the case was thoroughly satisfactory. The suprapubic wound speedily closed, the catheter was soon removed from the urethra, and, on the fourteenth day, the wound in the perinæum was indicated by a small granulating ulcer. On April 7, when the patient was discharged from the hospital, a large catheter (no. 13) could be easily passed along the urethra into the bladder, the urine was clear and gave an acid reaction; and the perineal wound had completely cicatrised. The author, in concluding his paper, remarks that, in the face of the excellent results of posterior catheterism in this difficult case, the proceeding may be warmly recommended to the profession for trial under similar conditions. Should its results be as favourable in the hands of others, and there is every reason to believe it would be so, then might this minor auxiliary operation be allowed a respectable position amongst surgical proceedings.

W. JOHNSON SMITH.

MASON ON RUPTURE OF THE BLADDER: OPERATION.—At a meeting of the New York Pathological Society on May 24 (*New York Medical Record*, July 22) Dr. Erskine Mason presented a specimen of rupture of the bladder taken from a man aged thirty-two, who was admitted into Bellevue Hospital on May 13. On May 10 the patient was arrested for intoxication, and was confined in a station-house. Shortly afterwards he complained of inability to pass his urine, and applied for relief. Instead of obtaining assistance, however, he was deluged with cold water. On the following day he was taken to the City Prison (Tombs), where he remained until his admission to the hospital. At the prison his urine was drawn twice.

When Dr. Mason saw him at the hospital he was perfectly rational; had a small, feeble pulse, anxious countenance, and the abdomen was swollen, the

upper portion being tympanitic and the lower portion dull. He complained only of vesical tenesmus. The scrotum was somewhat discoloured, giving rise to the possibility of injury of the perinæum and consequent rupture of the bladder. No other marks of external injury were discoverable. A moderate-sized catheter was passed into the bladder, and twenty ounces of pure urine were evacuated. There was evidently no stricture. A rectal examination was made by passing the forefinger well up into the rectum, behind the prostate. A little to the left of the latter a distinct swelling was recognised, containing fluid. The diagnosis was then made of rupture of the urethra, behind the triangular ligament, with effusion into the peritoneal cavity.

As the only hope rested in an operation, the usual one for lithotomy was performed. As soon as the incision was made, the finger being passed into the bladder, came into contact with, and passed through, a rent into the posterior wall of the viscus. The latter was firmly contracted, and no urine flowed through the incision. A silver catheter was then passed through the rupture into the peritoneal cavity, and ten ounces of a somewhat turbid fluid were drawn off. The patient sank, and died twelve hours after the operation, and on the fourth day from the commencement of the trouble. The necropsy was made a few hours after death, and revealed general peritonitis, with considerable urine in the cavity of the abdomen. The intestines were matted together by recent adhesions. In the posterior wall of the bladder the rent was discovered, measuring one and a-half inches in length, the edges being everted, and presenting a sloughy appearance.

In conclusion, Dr. Mason gave the following statistical account of the operations which had been performed for rupture of the bladder. The first who did this operation for rupture of the bladder was Dr. W. J. Walker, of Boston, 1845. The operation was done twenty-four hours after the accident; the patient recovered. It was done in this city by Dr. Willard Parker, a few hours after the rupture had occurred; the patient recovered. Dr. Mason has had four cases of rupture of the bladder, where he did this operation, and two recoveries. His first case was in 1871. The operation was done on the third day after the accident; the patient recovered. The second case was in 1873, operation being done a few hours after the accident; the patient recovered. The third case was operated on twenty days after the accident; he lived fourteen days. He says that, in seven cases where this operation had been done, there had been four recoveries, a most gratifying result when compared with the seventy-eight cases of rupture of the bladder collected in 1851 by Dr. Stephen Smith, which were treated without operation. Among these there were but five recoveries.

CONNER ON A PISTOL-SHOT WOUND OF THE HEART; DEATH THIRTY-EIGHT MONTHS AFTERWARDS.—The case is reported in the *Cincinnati Clinic* of May 27, (abstract in *American Journal of Medical Sciences* for July) by Dr. P. S. Conner. A lad, aged fifteen, was accidentally shot, December 31, 1872. The ball entered over the sixth rib about one inch posterior to the right lateral line, penetrated the thorax, and lodged. Hæmorrhage was quite profuse at the time, but had ceased when Dr. Conner saw him sixteen hours afterwards. Severe pleuro-pneumonia was soon developed, followed by pericarditis and endocarditis,

but these subsided by the twentieth day and convalescence steadily went on. Examination showed extensive valvular lesions of the heart. There was marked anæmia, with want of muscular strength, and this continued till his death, thirty-eight months after the injury. At the necropsy, the heart occupied a space much larger than normal. The pericardial sac was completely obliterated by adhesions, and the heart when removed measured twelve inches in its greatest circumference, and weighed twenty-one and a half ounces. Old pleuritic adhesions existed on the right side, easily broken down except opposite the cicatrix of the external wound, where a very firm band was found. Four ounces of serum was in the pleural cavities and over a pint in the peritoneal cavity. The abdominal viscera were all in normal condition. The left lung and upper and middle lobes of the right lung were healthy. An incision made into the lower lobe through the denuded space already referred to showed hepatisation, and imbedded in the lung-tissue at a depth of half an inch, unencapsulated and with no evidences of specially diseased tissue about it, was a spiculum of bone a half inch long, one-eighth inch wide, and a line in thickness, evidently a splinter from the rib. No cicatrix of a ball-wound could be found. Upon the anterior surface of the right ventricle, one inch to the right of the ventricular septum and an inch below the auriculo-ventricular septum, was an indurated patch involving the entire thickness of the wall with a very faint cicatricial marking externally. Upon opening the ventricles, there was a canal about one-fourth of an inch in length with smooth cicatricial orifices. Upon the ventricular face of the left anterior segment of this valve, was a vegetation almost circular in shape, one-fourth inch in diameter. The posterior segment was torn, and its remaining surfaces covered with vegetations of large size, some not less than one inch in length. An opening with ragged edges, and covered with vegetations on both sides, established communication with the right auricle at a point about one-third the distance from the fibrous ring to the opening of the superior cava. Upon the posterior wall at the point opposite in the normal position of the parts was a very distinct somewhat stellate cicatricial patch. At the root of the lower lobe of the right lung, just below the bifurcation of the main bronchus of this lobe, the ball was found lodged, completely encapsulated. It was conical, three-eighths of an inch long, one-fourth of an inch in diameter.

VALERANI ON A CASE OF CONGENITAL MACROGLOSSIA SUCCESSFULLY TREATED.—Dr. Valerani, of Casale, relates in the *Giornale della Reale Accademia di Torino* (Fasc. 15-18) that in July 1875 there was brought to him a female infant, about two months old, presenting a condition of the tongue which, the mother said, had existed from birth. There was hypertrophy, with elongation of the organ, which projected about four-fifths of an inch beyond the lips. Sucking was rather difficult, and the lips and chin were constantly moistened with saliva, which flowed from the mouth, which was always open. As sucking was not altogether impeded. Dr. Valerani advised the mother to wait a few months, so that the child might be better able to bear operation. In the following December the child was again brought to him. The hypertrophy of the tongue had considerably increased; the projecting portion was drier than the part within

the mouth, and had a violet colour; the saliva escaped continually; and the aperture of the mouth was widened. Amputation of all the portion of the tongue projecting beyond the dental arches was proposed, and consented to by the mother; and the operation was accordingly done by means of the galvanic wire, without the loss of a drop of blood.

RUGGI ON THE SEAT OF FUNGOUS SYNOVITIS OF THE KNEE-JOINT.—Dr. Ruggi, in a paper published in the *Bulletino delle Scienze Mediche di Bologna* (series 5, vol. ix.), pointed out that, in cases of disease of the knee affecting the articular surfaces of the femur and tibia, the patient seeks instinctively to diminish the contact of the bones by bending the limb. In some cases, however, the limb remains extended; and Dr. Ruggi has published in the same for April and May a case in which he believes that he has found an explanation of this. The patient was a scrofulous old woman, in whom, after a blow, the right knee became swollen, and so painful that she was obliged to keep the limb immovable. She was under Dr. Ruggi's observation seven months, during which time she kept the limb extended; the knee was swollen, hot, and painful; the skin was sound; the capsule of the joint was full of fluid; the patella was pushed forward, the condyles of the femur retaining their proper relations; all attempts to approximate the patella to the femur or to bend the leg were attended with extreme pain. The patient had fever, diarrhoea, and want of sleep, and it was at last found necessary to perform amputation. On examination, the disease was found to be limited to the articulation between the femur and patella. The cartilage encrusting the patella was ulcerated, and there was a corresponding spot of ulceration in the external condyle of the femur. The articular surfaces of the femur and tibia were sound. The inflammatory process had, then, commenced in the anterior part of the articulation.

This case, Dr. Ruggi says, demonstrates that fungous synovitis may be limited to the spot where the patella comes into contact with the condyles of the femur, and in this way may be explained the symptoms in cases where the limb is extended. There would then be two forms of synovitis of the knee, distinct in their seats and in their symptoms. While flexion of the leg on the thigh is the best means of relieving pain in cases of inflammation of the femoro-tibial articulation, extension of the limb, Dr. Ruggi states, is the most favourable position in cases of diseases of the femoro-patellar articulation. In extension, all the anterior soft parts of the knee are relaxed, especially the upper synovial sac of the patella, while in flexion all these parts are tense, and the patella is pressed against the anterior surface of the condyles of the femur; the same may be said of the synovial capsule lying under the quadriceps muscle.

A. HENRY, M.D.

SMITH ON UNRECOGNISED DISLOCATIONS OF THE SHOULDER-JOINT.—Dr. Stephen Smith, Surgeon to the Bellevue Hospital, New York, writes as follows in the *Archives of Clinical Surgery* for July. Several years since, I had occasion to examine the shoulder of a patient who had some time before received an injury by a fall. The case had been treated as a bruise, and was apparently convalescing favourably. There was an evident loss of rotundity in front of and below the acromion, and prominence

posteriorly; the arm hung by the side, the elbow being thrown slightly forward and outward; there was very good motion except in abducting the arm, and in placing the hand upon the head; the power of using the arm was satisfactorily increasing. On careful examination of the shoulder, it was discovered that the head of the humerus was behind the glenoid cavity, but in close contact with its posterior margin. The dislocation was easily reduced by traction on the arm, in a direction forwards and downwards, with immediate relief to the more prominent symptoms.

A second case recently came under my observation. A blind man stumbled and fell, striking upon the shoulder. He suffered somewhat from the immediate effects of the injury, and after a few days applied to a physician who examined the shoulder, and decided that he was suffering from a sprain. I saw him several weeks after the injury and found the condition of the shoulder quite like the preceding case. There was a perceptible loss of fullness under the anterior part of the acromion, and prominence posteriorly; the arm hung by the side as in the former case; he could move it freely except upwards and backwards, and in these motions he was not altogether restricted. He stated that he was daily gaining more and more use of the limb. It was readily reduced by moderate traction forwards, and with a marked snap. On the following day re-dislocation occurred, on slight movement of the arm forward. On being restored, firm support was given to the arm, and the recovery was complete.

Dislocations backward of the upper extremity of the humerus are of two varieties, viz.: subacromial, and subspinous. The second variety, subspinous, is not difficult of detection, as the deformity is very marked, and the arm severely crippled in its movements. Subacromial dislocation, however, is not so readily diagnosed.

In both of the cases given, the dislocation had escaped recognition by the physicians who first examined them, and in both, the patients were apparently satisfactorily recovering from what was believed to be a sprain. There is little doubt that they would have recovered with very useful limbs, new articulations being forward. Is it not probable that this form of dislocation occurs much more frequently than our surgical authorities lead us to believe? These cases are not exceptional. Many of the reported cases were not correctly diagnosed at first. Even Sir Astley Cooper failed in two instances to recognise the nature of the displacement at first, as did also Bransby Cooper in his single case.

Mr. Le Gros Clark has recently had a similar case under treatment (*St. Thomas's Hospital Reports*), and inclines to regard it as a partial dislocation, the head resting on the posterior edge of the glenoid cavity, the capsule being unruptured.

TILLAUX ON A CASE OF SUBCORACOID DISLOCATION OF THE SHOULDER TAKING PLACE SEVERAL TIMES A DAY.—A case of this kind is under the care of M. Tillaux (*Gazette des Hôpitaux*, August 12). The patient is a man aged twenty-five, who dislocates his shoulder daily, many times a day, and reduces the dislocation himself. Long afflicted with epilepsy, the fits of which recurred about every month, and always at night, this young man, who worked at a grocer's, one night about ten months ago, fell out of bed in a fit. When he recovered

consciousness, at the end of about half-an-hour, he perceived that he could not bring his right elbow to his body, and that the movements of his arm were very limited; there was a subcoracoid dislocation. After some efforts he felt a cracking in the shoulder, and the arm resumed its proper shape and functions. The same dislocation occurred two or three months later, but reduction again occurred spontaneously. The patient changed his occupation, but in vain; the limb was dislocated at first twice or thrice a month, then every day, and ultimately several times a day. Generally the luxation takes place involuntarily, but he can do it at will by bringing the arm outwards, a little backwards, and upwards. This extreme facility of displacement being a great infirmity, M. Tillaux hopes to remedy it by the application of an apparatus which, enclosing the shoulder, will place an obstacle in the way of the great abduction of the arm.

REVILLOUT ON A CASE OF FRACTURE OF THE SKULL WITH ESCAPE OF CEREBRAL SUBSTANCE.—In the *Gazette des Hôpitaux*, August 12, Dr. Revillout mentions the following case under the care of M. Tillaux in the Lariboisière Hospital. The patient, a man, on July 1 last, fell from a height of 14 mètres (42 feet) on to the macadamised road. He fell on his head. His forehead was cut open transversely for a length of about 12 centimètres, not far from the roots of the hairs. The wound extended equally on each side of the median line, but on the left side it was narrow, whilst on the right the bone was broken open for a centimètre at least, and the crushed cerebral substance was seen protruding. The patient suffered no cerebral effects except from the eighth to the thirteenth day. On July 13, he recovered consciousness and since then has gone on well. At the present time, the wound is closed. The loss of cerebral substance has not been accompanied by any functional disturbance or any pain.

W. DOUGLAS HEMMING.

BALFOUR ON SULPHUROUS ACID AS AN ANTISEPTIC FOR COUNTRY PRACTICE.—In the *Edinburgh Medical Journal* for August, Mr. John Balfour of Leven advocates for country practice, where the usual appliances for antiseptic surgery are not available, the use of the sulphurous acid wash, originally recommended by Dr. Dewar of Kirkcaldy. He has used it for many years with great satisfaction in all cases of factory accidents, cuts, and lately in a case of amputation at the shoulder-joint. In the proportion of one in twelve of water, it at once alleviates pain, minimises suppuration, is easily applied, and facilitates dressing the wound, while it costs almost nothing. When the fingers are the parts injured, a large tea-cup filled with the wash is put by the patient's side, and into this the injured part, covered with the thinnest rag to be had, is dipped as often as desired. Should the injured part be the hand or any other part of the body, it is supported on a pillow covered with gutta-percha tissue or oilskin, and the wash is applied by means of a little tow, which is allowed to remain in the cup.

MATERIA MEDICA AND THERAPEUTICS.

BÖCKER ON INHALATIONS AFTER TRACHEOTOMY.—Dr. A. Böcker read a paper at the Hufeland Society, of which the following is an abstract (*Deutsche Medicinische Wochenschrift*, July 8, 1876.) He states that the success obtained by him through the use of inhalations after tracheotomy has induced him to publish this paper, containing the results of his experience in seventeen cases. Inhalations of vaporized substances before tracheotomy have long been in use. Lime-water, salt and water, solutions of chlorate of potash, chlorate of soda, and chlorinated soda, and more lately carbolic and salicylic acids, have all been employed. Küchenmeister seems first to have conceived the idea of dissolving the membranes formed in croup and diphtheria. He showed that lime-water would dissolve the membrane in croup. Then Fieber recommended its local use, and Biermer published a case in which, after tracheotomy, one pint of lime-water to thirty of distilled water was used as

a vapour, and he attributed the recovery to this means. Goltstein, of Breslau, applied the lime-water directly to the throat with the aid of the laryngoscope, with good results.

In 1867, Bricheteau and Adrian published a paper in the *Bulletin de Thérapeutique*, entitled 'Recherches sur la solubilité des fausses membranes diphthériques.' They stated that the membrane of croup was very soluble in a solution of lactic acid. Lime-water was less active. Chlorinated lime and soda were still weaker, and other reagents, including the soda and potash salts, were quite inert. Weber, of Darmstadt, was the first to use lactic acid extensively, and he reported his success as overwhelming, and that he had latterly quite abandoned tracheotomy. There are, however, some reasons to doubt if his cases were really all membranous or true croup. Dr. Böcker purposes once more to try lactic acid, though it has not succeeded well with him, and has the disagreeable property of acting as an escharotic on the general mucous membrane of the mouth and throat, so that the little patients object to it. He uses various solutions, and places the inhalation apparatus only about six inches from the cannula. He refers, also, to a paper by Dr. Burow, jun., and to a dissertation by Dr. Vergueiro, who quotes cases of success with this method from Dr. Burow and from Dr. Böcker. The ages of the latter's patients were as follows :

1	under 1 year of age, who died	
2	between 1 and 2 years, both died	
3	" 2 " 3 " "	1 "
3	" 3 " 4 " "	1 "
2	" 4 " 5 " "	both recovered
3	" 5 " 6 " "	1 died
1	" 6 " 7 " "	
1	" 8 " 9 " "	
1	over 10 years of age	
17 cases with	6 deaths.	

There was another death, due to a complication which he regards as successful *quoad* operation. Dr. Burow, jun., has saved six out of eight cases or 75 per cent. whilst he lost seven out of ten before he adopted this method—thus only saving 30 per cent. without inhalation. The vapours used by Dr. Böcker were $\frac{1}{2}$ to 1 per cent. solution of sodium chloride, solution of lactic acid, and solution of carbonate of potash—the salt solution being the one chiefly used.

[The reporter has had considerable experience of the results of tracheotomy, having witnessed the operation more than fifty times, besides having performed it himself. The result of the cases personally known to him is identical with the statistics of Dr. Buchanan, of Glasgow, who out of more than forty cases saved one-third. Exactly one-third of the cases known to the reporter made a permanent recovery. If all those who lived a week or two after the operation were included, the total of recoveries would be over 40 per cent. The question of age is, however, one of such vast importance, that it is doubtful if Dr. Böcker's recoveries were really much assisted by the dilute saline solutions. It will be noted that no recovery took place under two years of age. There is, however, in this paper sufficient encouragement for the further trial of the method, and there certainly seems little danger in the addition of a little chloride of sodium to the vapour of water, already largely used by English as well as by foreign surgeons.—*Rep.*] W. BATHURST WOODMAN.

OSGOOD ON NITRITE OF AMYL IN INTERMITTENT FEVER.—In an article communicated to the *Philadel-*

phia Medical Times for July 8, Dr. Osgood states that, in a case of intermittent fever which came under his notice, the patient being in the cold stage, it occurred to him that, since his peripheral capillaries were in a state of contraction (as in all cases of chill), it would be perfectly logical to expect that the vaso-motor spasm would be overcome by the nitrite of amyl. He administered the remedy by inhalation, using about six drops. The remnant of the chill at once disappeared. He did not, however, consider this a fair case, because the chill-period was nearly over before he saw the patient.

A few days later, a German was brought to the hospital, in the acme of the cold stage; face cyanotic, teeth chattering, and he shaking himself to pieces generally. Dr. Osgood at once administered the amyl. Within forty seconds the chill was gone, and the patient complained of too much warmth. Five minutes later, the patient began to feel chilly. A few inhalations of the remedy again flushed the surface, and there was no subsequent return of the chill; but fever came on as usual.

In a third case, the chill was more obstinate, or the remedy less effectual, for, although the chill momentarily and at once aborted, it returned several times, each recurring chill, however, being feebler than the preceding one, before Dr. Osgood fairly conquered it, which he did by large doses (gtt. xx-xxx). It may be that a heavy dose of the amyl (say f3j) given at the outset would abort a chill at once, and finally. As yet, he has never administered so large a quantity as one drachm, excepting in a case of angina pectoris, mentioned in the *American Journal of the Medical Sciences* for October, 1865. In this case, the patient was a delicate lady; but she was not in the least disturbed by the large dose. Dr. Osgood says that it is premature to set the proper value on the nitrite of amyl as a remedy in malarial fever. In three cases it aborted the chill, having no especial effect upon the later stages, except more or less to shorten them.

BOUCHARDAT ON THE HYGIENIC TREATMENT OF POLYURIA.—In the *Bulletin Général de Thérapeutique* for July 30, 1876, M. Bouchardat has a paper on the hygienic treatment of polyuria; including, under this name, the excess of production or insufficiency of elimination of uric acid or the bi-urates. According to the author, attention must be specially directed to the food, the excretions, exercise, and the skin.

Food should be taken sparingly, well cut and thoroughly masticated. Sorrel, sorrel soup, and tomatoes should be forbidden, and also asparagus and beans if their use cause renal pain or slight deposit in the urine. Meat of all kinds may be allowed, but only moderately; still more sparingly must we allow eggs, fish, lobsters, shrimps, shell-fish, and old cheese; milk is often useful. Almost all seasonable vegetables are good, particularly spinach, endive, lettuce, artichokes, Jerusalem artichokes, celery, carrots, parsnips, and potatoes. The last named are useful, and should take the place of some of the bread with the meal after the English fashion. Ordinary radishes may be advantageously used daily. Cabbages, cauliflowers, Brussels sprouts, mushrooms, truffles, chestnuts, beans, peas, lentils, are not forbidden, but their use must be regulated according to their effect on the digestive apparatus. The daily use of cresses or salad is indicated. All fruits, if the stomach bear them well, may be served

daily. Olives, almonds, walnuts, hazel-nuts, and pistachio nuts must be served moderately. Good chocolate is allowable. If coffee provoke urinary secretion, it may be advised. Brandy and liquors should be avoided; very little beer allowed, and for alcoholic drink a light white or red wine diluted freely with water. White sparkling wines are contra-indicated as well as gaseous drinks, as, soda-water. On waking, going to bed, and with meals, sufficient watery drink should be taken to give about a litre and a third of urine. This watery drink should consist of pure water, Vals water (Saint Jean), decoctions of dogs' grass, of ash leaves, linseed, etc., or better still, a litre of water in which is dissolved one or two teaspoonfuls of powdered Seignette salt.

Excretions.—The bladder should be regularly and completely emptied every six hours at least. In order to attain this end, a good walk after each meal, and the efforts necessitated by defecation, will be found useful. A motion of the bowels should be obtained daily at a regular hour. If necessary, in order to ensure this, one or two spoonfuls of white mustard or linseed should be taken with the morning meal. If this do not suffice, on rising in the morning, a spoonful, of varying size according to its effect, of powder of tartrate of potash and soda (Seignette's salt) may be taken in a glass of liquorice water, lemonade, or orangeade. This should be continued until regularity is produced.

Exercise.—The powers should be exercised as much as possible, carefully avoiding cold not followed by reaction. Exercise of the arms is especially useful. Elastic apparatus may be used for this purpose in the rooms. Among ordinary exercises, the patient should choose that which is most agreeable to him, and should continue it until he is in a good sweat; then he should change, rub himself quickly and thoroughly with dry cloths, and take precaution against colds. Exercise every day, according to power, is the only efficacious prophylactic remedy.

The Skin.—On rising, rapid sponging with water, followed by long and quick rubbing with cloths, with a brush, flannel, or India-rubber, then kneading with the hand with some drops of perfumed olive oil. If exercise cannot be taken, the dry rubbings and kneadings should be sufficiently energetic to warm the whole body, and they should be supplemented by long and deep inspirations.

Every week from one to three baths containing 10 grammes of carbonate of potash, 2 grammes of essence of lavender, and 5 grammes of tincture of benzoin should be taken. These baths should be followed by long frictions and kneadings. If the patient take a season of river or sea baths, they should be of very short duration and followed by rubbings and exercise.

DUJARDIN-BEAUMETZ AND AUDIGÉ ON THE TOXIC PROPERTIES OF GLYCERINE.—In the *Bulletin Général de Thérapeutique*, July 30, 1876, is a very interesting account of an elaborate series of experiments by MM. Dujardin-Beaumetz and Audigé on the poisonous effects produced by large doses of glycerine. The experiments were made on dogs by injecting the substance under the skin. The following are the conclusions at which the authors arrive. 1. Glycerine chemically pure causes in the dog, in twenty-four hours after being introduced under the skin, deadly effects where the dose is in the proportion of 8 to 10 grammes (120 to 150 grains) to a

kilogramme, (35 ounces, 120 grains) of the weight of the dog. 2. The toxic effects (acute glycerism) are comparable within certain limits to those of acute alcoholism. 3. The necroscopic lesions in glycerism are analogous to those of alcoholism, which tends to induce the belief that the toxic effects of these two substances are almost the same. 4. From a therapeutic point of view, there may, therefore, be some danger in introducing glycerine into the economy in too large quantities.

MARTINEAU ON SUBNITRATE OF BISMUTH IN THE INTESTINAL HÆMORRHAGES OF TYPHOID FEVER.—In the intestinal hæmorrhages which supervene in the course of typhoid fever Dr. Martineau (*Lyon Médical*, August 6, 1876, from *Gazette des Hôpitaux*) recommends, on account of its perfect harmlessness, subnitrate of bismuth. He administers this remedy every half hour, until the cessation of the hæmorrhage, in powders containing one gramme (fifteen grains). This method is derived from the practice of Monneret who, considering that bismuth acted specially as a mechanical agent, so to speak, covering the inflamed and ulcerated mucous surfaces, always employed it, in preference to giving half-doses. In five patients, whom Dr. Martineau has thus treated, the result has been well and rapidly attained.

DE CÉRENVILLE ON THE INJECTION OF CHLOROFORM FOR THE RELIEF OF OBSTINATE SCIATICA.—In the *Lyon Médical*, for August 6, appears a summary of a paper by Dr. De Cérenville, of Lausanne, from the *Bulletin de la Société Médicale de la Suisse Romande*, on this subject. Dr. De Cérenville has employed this method of treatment in many cases, with the best results. He chose old standing cases of true sciatica, which had been previously treated by blisters, iodine, revulsion of all kinds, even red-hot iron; he practised the injection in the sciatic region, in the middle of the thigh, in the calf, where the pain was specially referred to the perineal branch, and he obtained very rapid cures. In some other cases he has noted only relative success, that is to say, there has been a reappearance of the pain at the end of some days. Dr. De Cérenville has remarked two accidents of which it is well to warn practitioners desirous of benefiting their patients by injections of chloroform.

On two occasions, he observed complete anæsthesia of the leg in which the injection had been made. This anomaly lasted two days, and disappeared as it had come, suddenly. The puncture had been made in the middle of the thigh, on the posterior part, and the injection had probably penetrated into the sheath of the nerve, or very near it.

In another case of the injection in the upper part of the calf, there was noticed a very painful swelling, which yielded to frictions of mercurial ointment and emollient poultices. Besides these, the author has seen no inconvenience arising from the chloroform. The quantity of the substance employed each time was about fifty drops.

OBSTETRICS AND GYNÆCOLOGY.

GOLAY ON A PECULIAR DEFORMITY OF THE UTERUS; CARCINOMA OF THE RIGHT OVARY; ATROPHY OF THE LEFT OVARY; ABSENCE OF MENSES.—At a meeting of the Anatomical Society of Paris (*Progrès Médical*, August 19) M. Golay narrated the case of a woman named Heimberger, aged thirty, a laundress, who was admitted into the Beaujon Hospital under the care of M. Matier and M. Lepine on March 21, 1876. During childhood she had been treated for mesenteric disease, and since that time her belly, without being painful, had always been rather large. She had always some cough, but her antecedents showed no signs of pulmonary tuberculosis. Until last year, she had enjoyed substantially good health.

She had never menstruated, nor had she ever had vicarious hæmorrhages; she had never felt pain about the loins or any other indisposition recurring periodically. She had never suffered from leucorrhœa.

She first perceived some enlargement of the belly in January, 1875, but did not remember on which side it began. This gradually increased, but without discomfort or pain to the patient, until, six months since, it reached an enormous size; and since that time the patient suffered occasionally from oppression, especially when walking or tired. The functions of the bowels and kidneys had always been normal, and the digestion and appetite good. For eight or nine months the patient had been becoming thinner and losing strength, and for two or three weeks there had been permanent infiltration of the legs.

On admission, the upper half of the body was greatly emaciated, while the abdomen was greatly distended; there was considerable inflammation of the lower extremities. The face was very pale, but did not present the cancerous tint. Respiration was very rapid (52 per minute), and the patient complained of beating of the heart. The abdomen was very large, projecting forward, on the right side rather more than on the left. At the level of the umbilicus was a soft, reddish, painless, depressible tumour of the size of a walnut. Palpation revealed general and considerable resistance of the abdomen, which was very hard throughout almost all its extent, only some few points being found slightly depressible.

The general sensation was that of an enormous solid tumour, occupying the whole abdominal cavity, and having no lateral mobility. Sharp percussion did not give any sensation of fluctuation, which could only be perceived by placing the left hand flat on the belly, and giving light taps with the right hand on the abdominal walls. The abdomen was dull throughout, and only on the flanks was there any resonance. These results were not altered by change of position.

Vaginal examination was difficult, owing to the presence of a perfectly intact hymen, and the unwillingness of the patient. The vagina was normal, the cervix rounded, raised and slightly displaced to the left. The body of the uterus was firm, and very mobile. Abdominal palpation comprised with vaginal exploration made the independence of the tumour and the uterus more certain. The diagnosis was of a large tumour, half liquid, half solid, and perhaps more solid than liquid; a multilocular cyst developed at the expense of both ovaries, and accompanied with some ascites. The heart-symptoms were not very remarkable, except for frequency of beat. Pulse 140, small, almost insensible. Respiration was very rapid (52). Auscultation in front revealed nothing abnormal.

The next day, owing to the great oppression of the breathing, the abdominal tumour was punctured at one of the most fluctuating points. Only a few drops of blood flowed; but on withdrawing the instrument about 500 grammes of serous, sanguinolent, and ascitic fluid escaped. A second puncture was tried in another fluctuating point, but only black blood escaped. The patient breathed with less difficulty, and the skin was less tense, while it was easy to make out the edges of the tumour. She died in the course of the night.

On opening the abdominal walls, about 500 grammes of ascitic fluid, strongly sanguinolent, flowed out. The tumour, which almost completely filled the abdominal cavity, was covered by epiploon much congested, reddish, and very vascular, the deep surface of which adhered to the anterior surface of the tumour. Some adhesions, easily broken through, attached the tumour to the small intestine. It sent no prolongation into the pelvis, and was attached to the uterus only by a pedicle of the size of a finger, composed of the proper ligament of the right ovary, much hypertrophied. This pedicle being divided, the tumour was removed from the abdomen, and was found to be regularly rounded, very large, and measuring a mean of forty centimètres (nearly 16 inches), in its different diameters. The surface was mammillated and traversed by numerous vascular branches. It was hard and elastic; some limited points only having a soft consistence. The tissue creaked under the scalpel, and exuded a juice when scraped. Sections were equally mammillated, and presented a white, yellowish, or rosy aspect. It was very vascular. Macroscopically the characters were those of a sarcoma, solid throughout, without evidence of any cyst. Nowhere could any gelatinous consistence be found. The whole mass weighed about 8,900 grammes (about 31 pounds). The uterus was very movable in the pelvis; it was longer than usual (seventy-five millimètres, instead of sixty or seventy); its breadth on the contrary was diminished (twenty-five millimètres instead of thirty-five). The fundus inclined to the right, and the right superior angle appeared much more developed than the left. The cervix, viewed externally, appeared

almost normal, but it was more cylindrical than usual in virgins; its external orifice was slightly dilated, and easily allowed a sound to enter the uterine cavity. Measurement of this cavity by the hystrometer gave sixty millimètres from the external orifice to the fundus instead of 52 millimètres (Courty), or 45 millimètres (Richet). On opening the uterus it was found that the cavity of the cervix exceeded the cavity of the body by a centimètre. The latter curved towards the right tube in the form of a conical canal, so that the angle corresponding to the insertion of the left Fallopian tube appeared diminished. The right Fallopian tube, free from adhesions to the tumour, had its walls red, thickened and hypertrophied. The right ovarian ligament, constituting the pedicle of the tumour, was red and thick, of the size of the index finger, much hypertrophied and presented at the point of division numerous gaping vessels visible to the naked eye. The left Fallopian tube appeared little altered. The left ovary was represented at the extremity of the left ovarian ligament only by a cyst of the size of a large pea, of a greyish aspect, opaline, and containing a little thickish liquid. This atrophy of the left ovary combined with the tumour developed in the right, accounted for the absence of the menses during the patient's whole life, and for many of the attributes of the male sex which she presented; as, almost complete absence of projection of the breasts, and the presence of numerous hairs round the areola, on the cheeks, the chin, and the upper lip. The external genital organs were well formed, and the voice had the feminine character.

Histological examination of the ovarian tumour showed a fibrous stroma with numerous cells of very various forms. The stroma formed very clear alveoli in which were found cells of varying size, but almost all large and of different shapes. These cells enclosed a variable number of nuclei. Numerous vessels were seen in the stroma. The tumour was therefore carcinomatous.

The details of measurement by the hystrometer are interesting, because some authors have shown that in difficult cases, where there is hesitation between a tumour of the ovary and a tumour of the uterus, deformity and lengthening of the cavity of the womb are signs of uterine fibroid. No doubt it is so in a great number of cases, but the present case proves that in certain tumours of the ovary which drag upon and lengthen the uterus, these signs may equally exist.

W. DOUGLAS HEMMING.

INGHAM ON SUDDEN EFFUSION OF BLOOD INTO THE LABIA OF PREGNANT WOMEN.—In the *American Supplement to the Obstetrical Journal* (June, 1876), Dr. J. V. Ingham reports two cases of sudden effusion of blood into the labia of pregnant women. In the first case the patient, twenty-five years old, who was five months advanced in pregnancy, tripped, but was caught by her husband, and was at the moment of tripping conscious of a sharp pain in her external genitals. Dr. Ingham found, on examination, the left labium enlarged to the size of an orange; it was dressed with laudanum and lead water, and gradually contracted and opened, discharging a fetid thick fluid, almost black. It finally healed, and labour came on without any difficulty at term.

The second case occurred in a woman, twenty-two years old, eight and a half months pregnant. She found a lump in her right labium, about the size of

a walnut on waking one morning. She was unconscious of any injury. The tumour increased and became painful, labour came on in a few days, and the tumour was opened as it interfered with the passage of the child's head; blood and pus escaped. The labium healed during the lying-in.

MCGAUGHEY ON TETANUS AFTER ABORTION.—Dr. James D. McGaughey relates (*American Supplement to the Obstetrical Journal of Great Britain and Ireland*, June, 1876), a case of abortion at two and a half months. There was profuse hæmorrhage, which was arrested by plugging the os uteri and vagina. At the end of a week, however, tetanus set in, the tetanic spasms recurring at intervals with opisthotonic rigidity, and the patient died on the fifth day.

MINOT ON RETRO-UTERINE HÆMATOCELE: OPENING INTO SMALL INTESTINE.—In the *American Supplement to the Obstetrical Journal* (June, 1876), Dr. Minot relates a case of retro-uterine hæmatocele in a prostitute. A free opening was made and a quantity of dark offensive blood escaped. While the house-pupil was syringing the cavity with Condy's fluid, the next evening, she uttered a cry of pain. Collapse and death ensued early the next morning. There were found at the *post mortem* examination numerous adhesions among the small intestines, the cæcum, and the sigmoid flexure; besides an opening from the small intestines leading into the hæmatocele. Between the uterus and the bladder, there was a cavity containing a clear yellow fluid.

FANCOURT BARNES, M.B.

MAIER ON TUMOURS OF THE DECIDUA.—Professor Rudolf Maier (Virchow's *Archiv*, May, 1876) has had two opportunities of observing new growths in the decidua, and the following are the results of his researches.

1. There are tumours of the decidua, true deciduomata.
2. These tumours, as it appears, only form in the uterus.
3. The new formations, so far as present knowledge goes, resemble in structure the areolar spaces of the early fenestrated decidua.
4. Primarily, the boundary-wall of these spaces and the contents are composed of only a single element, decidua cells.
5. Only very little connective tissue enters into the arrangement.
6. Single parts of the tumour are composed throughout of solid tissue, and others exclusively of decidua cells.
7. The vascular portion coincides primarily with the connective tissue portion, which in the true tumour tissue is only small, and chiefly present on the outer side of the tumour when it is in connection with the wall of the uterus.
8. The new formations soon form circumscribed nodular growths, soon broader wall-fixed expansions.
9. The occurrence of pregnancy or catamenial irritation has an influence on their formation.
10. By their faster or looser attachment to the wall of the uterus, they may acquire clinical and gynecological importance, quite independent of their possible interference with utero-gestation.

ROBERT SAUNDBY, M.B.

KIMBALL ON A SUCCESSFUL CASE OF EXTIRPATION OF THE UTERUS AND BOTH OVARIES FOR

FIBRO-CYSTIC DISEASE.—This case is related in detail in the *Boston Medical and Surgical Journal* for July 13. The patient, Mrs. W. J. B., was born in 1839, of healthy parents, and, so far as hereditary taints are concerned, with healthy ancestors. During girlhood and womanhood she enjoyed good health; commenced to menstruate at fourteen years of age, and menstruation had since been generally normal.

She was married in January, 1868, and was delivered of a daughter after a natural labour in Oct. 1869; she made a perfect recovery, and continued in good health till April, 1874, at which time she found a small bunch in the left inguinal region, apparently about the size of an English walnut. It gave her no inconvenience, except by the consciousness of its presence. She first consulted a physician regarding it in September, 1874. A rounded tumour, apparently about five inches in diameter, was found in the left and lower portion of the abdomen, movable, falling toward either dependent side, but not so far to the right as to the left. By examination the vagina was found to be normal; the uterus inclined to prolapse, but not very movable, and anteverted at the inner os. The os uteri appeared patulous, and the arbor vitæ showed very plainly on the posterior part of the exposed canal. The length of the uterine cavity was not determined, as it was found very difficult to introduce the sound beyond the inner os. The diagnosis of ovarian tumour, with possibly fibrous enlargement of the uterus, was ventured. In the latter part of the same month the patient consulted Dr. Kimball and Dr. Clapp, both of whom diagnosed ovarian tumour, and suggested operation. In September, 1875, she entered the Massachusetts General Hospital, where paracentesis was done by Dr. Porter, and fifteen and a half quarts of pale, yellow, serous fluid were removed. Three days later she returned home, where she remained very comfortable for a short time, but in about five weeks seemed as large as before the operation. The uterus became very much prolapsed, so that a Meigs's ring was worn to prevent procidentia. The patient became nervous and exhausted, and very much emaciated. Again she sought advice of Dr. Kimball, who, as before, suggested operation. On January 5, 1876 (that date being the middle of her menstrual month) the bowels had been thoroughly unloaded, the rectum cleansed by an enema of warm water, and the bladder emptied, etherisation was commenced at half-past eleven o'clock. The patient came slowly under the ether, and the operation was begun with the ordinary incision in the median line below the umbilicus. The abdominal walls were very thin, with but little adipose material. There then appeared a fleshy-looking substance, of the peculiar dark pinkish colour characteristic of fibrous growth. The tumour was tapped, and a quantity of straw-coloured fluid flowed freely through the cannula. The bulk of the tumour was greatly reduced, but there still remained a considerable fulness in the lower part of the abdomen. The sac was found quite adherent to the peritoneal lining of the upper anterior portion of the abdomen. These adhesions were carefully torn away with the fingers, and the sac brought out through the incision. There was no adhesion at the point of former tapping. Upon drawing the mass up, the pelvis was found to be nearly filled by a fibrous growth which formed the lower portion of the sac, from one to three inches in thickness, and gradually fading upwards into the thin walls of the cyst. The fibrous growth was

found to extend by prolongation to the uterus, and to be thoroughly blended with that organ, making one continuous substance. Both ovaries had small cysts in their substance.

As a preliminary measure the broad ligament was perforated upon the left side, to the left of the ovary, and a silk ligature was passed round it and firmly tied. The tissues between the ligature and the tumour were then divided. A considerable hæmorrhage from the cut surface occurring, a temporary ligature was applied, to prevent the bleeding from the tumour. It now became possible to bring out the whole mass through the incision, and the wire écraseur was applied at a point corresponding to the external os, involving the remainder of the broad ligament and the round ligament of the left side, the upper part of the vagina, and the round and broad ligaments of the right side beyond the right ovary. The wire was tightly drawn and twisted for security, and the mass removed by the knife. The écraseur was allowed to remain, and the stump was transfixed just outside of the loop of the écraseur with a curved trocar, which was arranged to give additional security against the return of the stump into the abdominal cavity. The abraded surface of the peritoneum, where the adhesions had been torn away, was carefully wiped with a dry cotton cloth to make sure that there was no hæmorrhage and that no clots were left, the wound was closed with silk sutures, and the stump cauterised with the hot iron. Care was taken throughout the operation to keep the room at a high temperature (70° to 80°), and to hold the flaps of the incision close to the tumour, that the abdominal organs might be as little exposed to the air as possible. No dressing was applied, except a folded compress of cotton cloth laid over the wound and upon the trocar and écraseur.

The operation occupied just an hour. The pulse and respiration continued natural throughout. Soon the patient began to recover from the effects of the ether. One fourth of a grain of sulphate of morphia was administered by hypodermic injection, and she was left in the care of the nurse.

The mass which had been removed was examined, and found to consist of twenty pounds of straw-coloured fluid and five pounds of solid material, the latter consisting of the cyst, the fibrous growth, both ovaries, parts of the suspensory ligaments of the uterus, and the uterus itself. The specimen is preserved in the medical museum of Harvard University.

On February 10 (thirty-seventh day) the wound was nearly well; and on March 10 the patient was able to go about her house, and attend to her duties.

SEYFERT ON A MEANS OF APPLYING SPONGE-TENTS.—In an article in the *Philadelphia Medical Times* for July 8, Dr. Seyfert remarks that sponge-tents are the best dilators at our service, but they are especially dangerous. Dr. Marion Sims writes: 'He who will give us an efficient, safe, and cheap substitute for sponge-tents will confer a great boon upon surgery. I know of no complete substitute, or I would be too willing to adopt it.' An instrument of this kind must not abrade the mucous membrane or retain secretions, and it should dilate equably and not too rapidly. More than one ingenious contrivance has sought favour as a substitute for compressed sponge, without succeeding in taking its place. The nearest approach, in Dr. Seyfert's opinion, to a safe and reliable tent has been made

by Dr. J. A. McFarraan, who has conceived the idea of preserving the use of compressed sponge whilst doing away with its dangers. His instrument consists of a small metallic or hard India-rubber tube, holding upon its perforated extremity a sponge-tent which is completely enveloped by a closely fitting thin piece of India-rubber. The India-rubber, while permitting the sponge to dilate to its fullest extent, prevents it from absorbing fluids from the canal and protects the cervical mucous membrane from abrasions. Water reaches the sponge through the tube, which has upon its vaginal extremity a distensible India-rubber ball for its reservoir. Instead of limiting the India-rubber covering to the tent, it may be made to envelope the entire apparatus, thus keeping the tube in constant contact with the water, which, by entering the perforations made in the tube, readily finds its way to the sponge.

BLAKE ON A CASE OF UNITED TWINS.—At a meeting of the New York Pathological Society, on February 23 (*New York Medical Journal*, April), Dr. J. E. Blake exhibited a specimen of monstrosity which was apparently in nearly every respect similar to the Siamese twins. Dr. Blake was enabled to present the specimen through the kindness of the consul for Sweden and Norway, who obtained it for Professor Nicolaysen, of Christiania. The twins weighed fifteen pounds, and were born at Tobasco, Mexico, and lived nine days. The father was a mulatto, the mother an Indian. One of the twins had the facial characteristics of the father, the other that of the mother. Both were girls. On examining the specimen it was noticed that the abdominal cavities were continuous, for when pressure was made on the abdomen of one the other became distended. The sternal bones seemed to be connected by a cartilaginous band. There was a common umbilical cord for both.

Dr. Blake remarked that the nature of the specimen in a practical point of view depended on the question whether the union was simply a fusion of the thoracic and abdominal parietes, or, as in the case of the Siamese twins, an union of the liver and other viscera. This point was of practical value, inasmuch as a case of the kind might occur at any time in obstetrical practice, and the question would arise as to the safety of dividing the connecting band.

ARNOLD ON INFANTILE MENSTRUATION.—Dr. C. D. Arnold relates in the *Louisville Medical News* for July 22 the following case. In September, 1873, Mrs. K. gave birth to a female infant of medium size and weight, there being nothing observed about the child unnatural to young infants, otherwise than unusually well-developed mammae. During a period embracing about twenty-four hours, commencing on the third day from birth, it discharged from the vagina, according to the mother's estimate, about one drachm of blood very much resembling in colour and consistency the healthy menstrual discharge of the adult female; then it ceased, but reoccurred at intervals of three or four weeks, until February, 1875, at which time the child died of croup, as is affirmed by the mother, no physician being in attendance. These discharges ordinarily lasted about one day (twenty-four hours), during which time the child was very feeble and quite cadaverous in appearance; but after the subsidence of the discharge it resumed its usual strength, colour, and sprightliness, though

its health was never considered good by the mother. In February, 1876, the mother gave birth to another female infant, which weighed eleven pounds, and which has had excellent health since birth, and is now an exceedingly large and healthy child for one of its age. Its mammae are large, but not so well developed as those of the former child. It has had, commencing about the end of the first week after birth, two periodical vaginal discharges of blood, each being accompanied by symptoms similar to those that characterised the discharges in the other; since which time nothing abnormal has taken place with the child.

DERMATOLOGY.

BULKLEY ON THE PATHOGENY AND TREATMENT OF HERPES ZOSTER.—In a paper in the *American Journal of the Medical Sciences* for July, 1876, Dr. L. D. Bulkley, of New York, relates a case in which a man had a large tumour on the right cervical region anteriorly. It disappeared in a few weeks under the use of arsenic, but the patient had herpes zoster in the right arm, the eruption being abundant and rather peculiarly arranged. The chest, front and rear, was entirely free from eruption, there being not even any red or tender spots, sometimes the evidence of aborted eruptions; the surface of the thorax was healthy. The eruption began at the back of the shoulder, but quite low down, at least an inch and a-half below the end of the humerus, and at about the same point, or a little lower down, on the anterior aspect of the arm. The groups here and elsewhere were pretty thickly set, and the inflammatory action was severe, as the vesicles here and also on the arm were large and flat, and many of them had run together, forming large, flat, bulbous masses. The eruption wound around the arm, from behind forwards, in a band of about two inches in width, and followed closely the course of the cutaneous branch of the musculo-spiral nerve. Passing thus around from the back to the front of the arm, the lower portion of the upper arm, and the entire anterior and outer aspect of the forearm were covered with two or three bands of vesicles, irregularly traced and often touching, so that about one-third of the entire circumference of the limb was covered by the eruption.

Upon the hand the disease occupied also the radial aspect and extended down even to the tips of the thumb and forefinger; the pain in the thumb was so great as to keep the patient from sleeping. The eruption appeared to be in about the fourth or fifth day, and the clinical history corresponded to this. The patient was given phosphide of zinc with nuxvomica, and did well.

After a comparison of the distribution of the eruption with that of the cutaneous nervous, Dr. Bulkley sums up in the following recapitulation.

1. Whatever may be the cause of the nerve-irritation, herpes zoster is always of nerve-origin; that is,

it is an inflammatory lesion of the skin wherein the local cell-action, resulting in the production of vesicles, is but a result of nerve-influence, a perverted cell-action caused by perverted innervation.*

2. From the almost constant changes found in the ganglia developed on the posterior or sensitive roots of the spinal nerves of the affected regions, we must infer that the trophic changes observed in the skin have to do with the sensitive nerves, which marks a certain advance in the study of the physiological relations of the trophic nerves or nerves of nutrition.

3. We are not to conclude, however, that zoster is the result of inflammation of the sensitive ganglia alone, for the entire nerve on the distal side of the ganglion has been always found to be inflamed, and abundant proof exists of eruptions of zoster due to various nerve-lesions, peripheral and central, injuries and disease of the transmitting nerves and of the cord and encephalon.

4. In certain cases the origin may be shown to be idiopathic inflammation of conducting nerves (as in Kaposi's case), or they may be affected by pressure or other alteration caused by the presence of a tumour (as in the case given here), or the disease may be the result of surgical or other injury.

5. The origin, therefore, of herpes zoster is a direct nerve-irritation and inflammation, and in ordinary, apparently idiopathic cases, the explanation of this is to be sought for in the same causes as give rise to neuralgiæ in general, some of which are traceable, many or not. The gouty habit, inducing neuralgia, can likewise give occasion to herpes; the direct exposure to cold of the terminal branches of a nerve, as in the head and neck or elsewhere, can cause painful excitation of the nerve itself, or neuralgia, and is equally a cause of zoster; malaria can originate neuralgia, and may not therefore some of the cases of zona be due to a malarial influence? Certainly the prompt action of citrate of iron and quinine in some cases might point to a malarial element.

6. In considering, then, the true nature of herpes zoster, we are rather led away from the skin lesion to the antecedent neuritis, whose manifestations are neuralgia, more or less marked, and disturbances of sensation in the area of nerve distribution, represented by hyperalgesia, hyperæsthesia, and anæsthesia, while at the same time other results of nerve disturbance may occur, as paralysis of muscles, trophic alterations in the tissues, and even necrosis and separation of bone. In other words, the eruption of zoster is an epi-phenomenon to a primary neuritis and neuralgia.

7. The clinical history and therapeutics of herpes zoster are in themselves almost convincing proofs of the neurotic nature of the disease. In most cases, especially in younger patients, the treatment is purely expectative, while in severe cases and in elderly persons the neuralgia is the principal element requiring attention, and this is remedied by measures directed to

the nervous system. In the majority of instances the nerve-irritation or inflammation subsides spontaneously, the whole train of morbid phenomena occupying about the same length of time taken by other self-limited inflammations, as pneumonia and erysipelas, while under certain circumstances the sequelæ require attention, as in other diseases. The local destruction of tissue is sometimes a troublesome feature in the way of ulceration or necrosis of the skin, or the neuralgia persists to a distressing degree even under the the most intelligent treatment.

8. Three therapeutic agents seem to have marked control over herpes zoster, whose cutaneous manifestations as well as painful element they appear to arrest. First, phosphorus, which used in the form of phosphide of zinc, one-third of a grain with one-third of a grain of extract of nux vomica, every three hours, will pretty certainly abort the disease if given early, as recommended by Dr. Ashburton Thompson. I should presume that the tincture of phosphorus, or what is known as Thompson's solution of phosphorus, as now used successfully for neuralgia, would have the same effect. I have not tried them in this disease, but have used the phosphide repeatedly and with most excellent results. Second, electricity: the galvanic current passed directly through the affected nerves, their trunks and peripheral distributions, will have the effect of causing the eruption either to abort, if used early, or will make the newly formed vesicles dry up much sooner than otherwise, and will pretty certainly check the pain. Third, quinine with iron will, I think, if pushed early in the disease, shorten the duration much and relieve many unpleasant symptoms.

Whether ergot, which has been of great service in neuralgia in the hands of some, would check this congestive neurosis I cannot say, but should hope much from it. The hypodermic injection of morphia, as we know, relieves the neuralgia, and if used early and repeatedly, might abort the disease by checking the nerve-irritation, especially if conjoined with atropia. Painting the surface with collodion or collod coating containing morphia would serve the same purpose; some assert that it is a very valuable measure. Ordinarily, the only local treatment required is protection of the inflamed surface; and this is best accomplished by powdering it with starch, and keeping a single thickness of muslin firmly applied, and left on till the vesicles are dried.

BOHN ON PEMPHIGUS ACUTUS NEONATORUM.—Dr. Bohn (*Fahrbuch für Kinderheilkunde*, i Band, 3 Heft) believes that the pemphigus of new-born children is connected with the desquamation of the epidermis, which takes place during the first week after birth. Nurses and midwives frequently bathe infants in water at too high a temperature, wrongly trusting to their own blunted sensations instead of using a thermometer. The consequence is that, the skin being very tender at that time, bullæ are produced. Dr. Bohn points out differences between this affection and true pemphigus, and shows that the idea as to its being a specific contagious disease is a mistaken one.

LEWIN ON ERYTHEMA EXSUDATIVUM.—Dr. G. Lewin (*Berliner Klinische Wochenschrift*, no. 23, 1876) states that the various forms of erythema are in some cases complicated by fever, and pustules may develop on the erythematous part which simu-

* I do not deny the influence also of capillary congestion, but as normal nutrition is rather the result of a proper appropriating of the needed nourishment and a giving up of unneeded and effete elements by the cells of a part, so under abnormal innervation the amount of fluid called for by the cells contiguous to the bloodvessels is larger than is needed, and forms the vesicles; by a lowered vitality endosmosis of the cells of the skin is in excess, as is seen outside of the body in dead animal tissues. Vaso-motor action, being also a trophic affair, is undoubtedly likewise disturbed.

late the pustules of variola. They may be complicated by inflammation in joints, in which there may be serous or purulent effusion, and ankylosis may follow; or endocarditis, with injury to the cardiac valves, may occur. In women especially, erythema is often dependent on inflammation and ulceration of the urethra. This was proved experimentally in the case of a man in whom irritation of the urethra reproduced an erythema which had previously disappeared. Erythema may occur in epidemics. The disease is believed by the author to be connected with the vasomotor nerves.

WINTERNITZ ON PELLAGRA.—Dr. Wilhelm Winternitz (*Vierteljahrsschrift für Dermatologie und Syphilis*, 1876, 2 Heft), after studying the disease in Italy and examining all the available literature on the subject, has come to the conclusion that the most various diseases which follow in the train of poverty and misery have been comprehended under the designation 'Pellagra'; that thus pellagra, as an individual special disease, which is confined to a particular area, does not exist; and that, further, if there is any specific disease attributable to unwholesome maize, its history has yet to be written, and that in any case pellagra is not that disease.

MEDICAL SOCIETY OF BERLIN.

March 1, 1876. *The Operative Treatment of Pleurisy*.—In making some remarks on Dr. Ewald's paper on this subject (the LONDON MEDICAL RECORD for July, page 324) Dr. Israel described a case of empyema following the rupture of a hydatid of the liver into the right pleural cavity, successfully treated by operation. The patient was a man, aged thirty-two. In September, 1872, an attack of icterus led to the discovery of a swelling in the liver, which was diagnosed as hydatid. In August, 1874, while staying at Kreuznach, the patient, while turning himself in bed, suddenly felt something burst within the belly; severe dyspnoea, oppression, and collapse set in. The echinococcus of the liver had burst into the right pleura. In December, 1874, he was admitted into the Jews' Hospital. The whole right pleural cavity was distended with fluid; the mediastinum and heart were pushed to the left. The liver was enlarged, extending beyond the umbilicus; and in the umbilical region a knob as large as an apple projected. Puncture was performed eight times; and on February 18, 1874, an incision was made. The first puncture gave exit to opaque tenacious yellow fluid, which coagulated into a solid mass on the addition of acetic or of nitric acid. Microscopic

examination showed hooklets and other fragments of echinococcus, pus-corpuscles, and a large number of cells with fatty nuclei. After repeated punctures, made with antiseptic precautions, the air being excluded, the exudation assumed to the naked eye the characters of pure pus. An incision made in the nipple line gave exit to a large number of echinococcus bladders swimming in pus. So long as, in consequence of the size of the echinococcus bladders, the pleural contents could not be evacuated, the temperature remained febrile; but, when on the eighth day a thick-walled mother-cyst, as large in its entire state as a child's head, was removed, and it became possible to cleanse the pleura more completely, the temperature fell to normal, and remained so during seven weeks, until Dr. Israel introduced a silver cannula through a piece of elastic catheter, the secretion of pus having been reduced to a minimum. The opening now rapidly became narrow, and high fever set in; complete cleansing was impossible, the double-current catheter could not be directed as was desirable, and the pus became offensive. This dangerous condition continued until the aperture was enlarged, and a wide silver cannula again introduced. The fever at once fell, and recovery took place with a very slight amount of deformity of the chest; the respiration was somewhat weaker in the right lung than in the left. Dr. Israel brought forward this case to prove the advantage of careful after-treatment, consisting in the cleansing of the pleural cavity. He was acquainted with nineteen cases in which this had been carried out; seven in the Jews' hospital, eleven in the practice of Dr. Fräntzel, and one in that of Dr. Traube. Of the nineteen, two were still under treatment, and six other cases were excluded on account of complications. Of the remaining eleven, complete recovery took place in ten without any fistula, and in one a fistula remained, as the patient would not allow the pleural cavity to be cleansed. Death took place in this case after some months. Of all the cases, one only was under twelve years of age. Of the six cases excluded, four had secondary pleurisy with phthisis—the disease in two being tuberculous, in a third, complicated with amyloid disease, and in a fourth with dysentery. In a fifth, amyloid degeneration of the kidneys and thoracic fistula existed before the operation was performed. The sixth case was one of empyema, developed during convalescence from a severe attack of enteric fever. The day after the incision was made, inflammation of the lung on the sound side set in, apparently in consequence of a chill, and the patient sank. Dr. Israel thought that his results after incision, being 90.9 per cent. of cures, were more favourable than those of Dr. Ewald, which were only 34.6 per cent.—Dr. Ewald objected to leaving a silver catheter in the opening, as the ribs might become carious, or the aperture might contract so closely about it as to render its removal difficult. Dr. Israel's proportion of successful cases was higher than he had been hitherto able to attain; and he could only wish that he might meet with such remarkably good fortune.—Dr. Israel explained that he did not advise that a silver catheter *à demeure* should be left in the wound. That would be very bad treatment. The cannula which he used projected only just beyond the inner surface of the chest-wall.

A Case of Cæsarean Section.—Dr. R. Cohn related the history of a case in which the operation was per-

formed on account of narrow pelvis, after ineffectual attempts had been made to deliver by forceps and by cephalotripsy. Sutures were applied to the uterus, and also to the abdominal wall. When the wound was healed, the uterus remained adherent to the abdominal wall. In the course of the case, a vesico-vaginal fistula was found to exist, and an operation was performed for its cure; but the patient died, and at the necropsy there were found diphtheritic inflammation of the mucous membrane of the vagina and bladder, and purulent peritonitis, pleuritis, and mediastinitis. The uterus was adherent to the cicatrix in the abdominal wall, and at its lower part to the posterior wall of the bladder. The external os uteri was obliterated, and the uterine cavity dilated.

March 15. *On Baths in general and Kreuznach in particular.*—Dr. Wiesbaden, of Kreuznach, read a paper on this subject, in which he advocated a more complete State-control of the public baths of Germany, the freest scope being at the same time given to local government.

Lactic Acid as a Hypnotic.—Herr E. Mendel read a paper on this subject. Referring to the observations of Preyer and Lothar Meyer, on the hypnotic properties of lactic acid, he said that its effects when administered by the mouth, either pure or in the form of lactate of soda, were uncertain, but he had found very good results from its use in enemata in a large number of cases. The dose of lactic acid was from five to twenty grammes (75 to 300 grains) mixed with an equal quantity of lactate of soda. The use of lactic acid was especially recommended, 1. In cases of insomnia in the course of or during convalescence from debilitating disease, after hæmorrhages, etc.; 2. As a calmative in the excitement of the insane; 3. As a remedy in certain psychoses, in regard to which its precise indications must be determined in the future.

March 29. *Lactic Acid as a Hypnotic.*—In commencing a discussion on Herr Mendel's paper, Herr Senator said that he had used lactic acid, either in divided doses, ten grammes (155 grains) being given in the course of a day; or in single doses of five to ten grammes in sugared water, or as lemonade. With the first-named mode of administration, no weariness was observed. On the other hand, a large single dose produced pure weariness, although lactic acid could not be compared as regarded strength and duration of action, with morphia or with chloral hydrate. There was, however, a troublesome after-effect, which had not been noticed by Herr Mendel nor by Lothar Meyer, the occurrence of rheumatic pains; these he had observed twice, once in a phthisical patient, the other time in a man who had frequent attacks of muscular rheumatism. Rheumatic pains had also been observed in giving lactic acid with other objects, such as the treatment of diabetes, etc. The occurrence of rheumatic pains after the use of lactic acid was of importance in regard to the theory of articular rheumatism; and he asked whether Herr Mendel or Herr Meyer had observed any thing of the kind.—Herr Mendel answered in the negative. The doses used by Herr Senator were too small; at least fifteen grammes should be given. He agreed with Herr Senator, that lactic acid was inferior to morphia and chloral hydrate.

The Preservation of the Teeth.—Herr J. Pätsch made a communication on this subject.

April 26. The President, Dr. Henoch, announced the death of Professor Traube, and made some

appropriate remarks on the event. As a mark of respect to Traube's memory, the ordinary business was deferred.

May 3. *Suppurative Parotitis in an Infant.*—Herr Senator related a case where suppurative parotitis occurred in a child six months old, in consequence of obstruction of Stenson's duct by a very fine piece of down. Relief was afforded by removing the foreign body and making an opening in the exterior of the cheek.

Intussusception in an Infant.—Herr Senator described the case of a child three months old, in which intussusception of the lower part of the bowel took place suddenly two days before the commencement of treatment. The invaginated portion could be easily reached with the finger *per rectum*. Reduction was effected, but the invagination recurred; and therefore injection of water or of air were tried for some time, and afterwards a rectum-bougie was introduced, and allowed to remain until thrust out by defæcation. During the first three days of treatment, there was frequent fæcal vomiting. On the fourth day distension and tenderness of the abdomen set in; the temperature in the rectum did not rise above 38·8° Cent. (101·8° Fahr.). These symptoms were relieved by the application of iced compresses to the abdomen. On the fourteenth day from the commencement of the illness, reduction was effected for the last time with the bougie, and remained permanent. The child was discharged from hospital eight days later, and had remained well for several weeks.—Herr Henoch said that Herr Senator's case further confirmed the observation, that there was little tendency to adhesion in cases of intussusception in early life. This rendered reduction easy. Nissen of Altona had effected replacement successfully in two cases by means of a sponge fastened to the end of an œsophageal bougie, and introduced into the rectum. It was, however, a question whether it would not be better to limit or altogether omit local manipulation. Even in Herr Senator's case, although it was successful, there were symptoms of diffuse peritonitis, which, dangerous in the adult, is especially perilous in early childhood. In adults, so far as he knew, attempts at reduction were not made in cases of intussusception, but ice and opium were used to quiet the bowels, to promote adhesion, and to favour the separation of the invaginated portion. He believed that in Herr Senator's case the possibility of such adhesion and separation was not very remote, as the stools became bloody as soon as he desisted from replacement of the intestine. These bloody stools are only the result of the various obstructions which the intussusception produces; and it may well be assumed that when the case has arrived at this stage, necrotic separation of the bowel may readily occur. He remembered a case which he had seen, together with two colleagues. The patient was a child, about six months old. It had the symptoms of intussusception—bloody stools, distension of the abdomen, severe vomiting; and, on introducing the finger into the rectum, the intussusception was distinctly felt. The first thought was to reduce the bowel, but the fear of breaking down adhesions and so producing peritonitis prevailed. For some days the child continued to suffer from vomiting, and discharged only a thin fluid from the rectum. On the third or fourth day, Dr. Henoch again introduced his finger, and when he removed it, the intussuscepted portion was discharged with an abundance of fæces. The

piece was about three inches long, apparently belonging to the sigmoid flexure. Diarrhœa and meteorism set in, but the child made a good recovery in no very long time. He believed that this result indicated that it was best to leave cases of the kind to nature, which had a good remedy in necrosis of the intussuscepted portion.—Herr B. Baginsky remarked that, while in most cases intussusception occurred in the lower parts of the intestinal canal, and the part became separated with tolerable rapidity, intussusception might also occur higher up in the intestine. A child, otherwise healthy, four and a-half months old, was brought to him, suffering from diarrhœa; for two days it had had irritating and bloody stools. It cried much, and was very restless. The fæces had a dysenteric character. The abdomen was somewhat distended; whether pain were produced by pressure, Dr. Baginsky could not determine. A tumour extending from the right upwards towards the left was felt below the umbilicus; its surface had a smooth feel; fluctuation could not be detected, but there was a peculiar retraction, a kind of hilus, at the border of the swelling. As Herr Baginsky had at the time several cases of dysentery in children under his care, he believed that the case was one of this disease, complicated with a movable kidney; for, to the touch, the swelling perfectly resembled a kidney. The child having died, a necropsy was made, and it was found that the tumour was formed by the intussusception of a large portion of the ileum into the cæcum. Through a remarkable elongation of the mesocolon, the cæcum and ascending colon were completely displaced, and a part of the ileum was invaginated into the cæcum. The vermiform appendix was adherent to the swelling, and was not found without much trouble. There were extensive adhesions; and, on making a section, the mucous membrane was found beset with hæmorrhages at several points, and covered with a dirty greenish-grey deposit. The bowel was permeable to a thin elastic catheter as large as a crow-quill. He thought this case remarkable for several reasons: first, because of the possibility of error in diagnosis; secondly, because the intussusception—at least as far as the pathological changes indicated—was probably somewhat chronic; and finally, because, in spite of the time during which the intussusception had lasted, separation had not occurred.—Herr Senator could not agree with Herr Hensch, but held that the first indication in all such cases was to attempt reduction, especially when the diagnosis of a mechanical impediment was certain. He agreed that the ice and opium treatment was the best in the case of adults, but it was so because intussusception low down in the bowel was much more rare in them than in children, and hence the diagnosis and reduction were more difficult. The fear of breaking down adhesions or of exciting peritonitis should not dissuade one from attempts at reduction. In any case, without reduction, when the strangulation continued, peritonitis and sloughing took place, unless the patient died sooner; but if reduction were effected, there might be no peritonitis, or, if it appeared, it was much more easily repressed than when its exciting cause, the strangulation of the intestine, was still present. He believed that in no case, where reduction was possible, ought we to hope for a natural cure, which rarely took place. In the case which he had related, there was no distinct peritonitis, but only slight irritation. He be-

lieved that he had prevented peritonitis by the reduction of the intussusception.—Herr Hensch remarked that, as in his case the invaginated portion was removed within a few days by sloughing, adhesions must have occurred at that period. It was impossible in any case to ascertain whether adhesions had taken place. The statistics of intussusception which he had examined showed that the separation of the invaginated portion had a favourable issue in a large proportion of cases, though occasionally slight meteorism occurred.—Herr Auerbach had had some years ago a weakly female child two years old under his care, which had suffered for some weeks from prolapsus, attended with severe pain. He gave small doses of strychnia, with the effect of producing relief, and the child recovered in a few weeks.—Herr B. Fränkel thought that intussusception was better treated by rest and opium than by mechanical means.—Herr E. Küster agreed with Herr Senator in recommending reduction, even when adhesion had taken place.—Herr Baginsky said that the insufflation of air into the rectum had undoubtedly been successful. He thought that in recent cases reduction might be attempted, and opium then given.—A few further remarks were made by Herr Cohn and Herr Senator.

ACADEMY OF MEDICINE IN PARIS.

July 25. *The Puerperal Murmur*.—M. Bouillaud resumed the question of the seat of the puerperal murmur. According to him, this murmur is seated in the pelvic arteries (iliac arteries). The uterine arteries would not be large enough to give rise to the murmur of pregnancy. Other abdominal arteries, however, notably the uterine, are capable of producing a puerperal murmur, but less intense than that of the pelvic arteries, which is the true murmur discovered by M. de Kergaradec.

August 1. *Nephritic Crises in Locomotor Ataxy*.—M. Maurice Raynaud read a paper on nephritic crises in locomotor ataxy. The object of the memoir was to show that sometimes, in the course of ataxy, attacks of pain occur, which from their locality and symptoms entirely resemble nephritic colic arising from calculus. In support of this opinion, the writer related a case in which he observed paroxysmal crises of extremely intense pain divided into three periods. In the first, the attacks were divided by intervals of nearly perfect health; in the second, they became to a certain extent subterrant, and gained in frequency what they lost in intensity; and finally, in the third, the paroxysms were gradually replaced by deep-seated and continuous pain. The characters of the pain, the retraction of the testicle, the anuria or ischuria, the vesical tenesmus, in a word, the entire assemblage of symptoms, resemble those of calculous nephritic colic to a misleading degree. However, there are some distinguishing characteristics; first, the long duration of the attack, which may last six or eight days uninterruptedly, a perfectly exceptional occurrence in true nephritic colic; then the frequent return of the paroxysms; finally, the absence of blood, pus, or gravel from the urine. In M. Raynaud's case, the necropsy showed the exactness of the diagnosis, by revealing the existence of typical sclerosis of the posterior layers of the spinal cord.

The Spirophore.—M. Woillez replied to some of the criticisms on the spirophore. He affirmed that its use does not involve the dangers attend-

ing the employment of Junod's cupping glass and the accidents of cerebral anæmia. He was of opinion that the union of the walls of the œsophagus does not allow air to penetrate into the stomach and intestines. If, however, experience show that the use of the spirophore has some disadvantages due to too great power of aspiration in the apparatus, it can easily be remedied by the less complete depression of the lever and the loosening of the India-rubber cloth placed round its neck. In reply to M. Depaul, who prefers artificial respiration by insufflation of the spirophore, M. Woillez declared his disbelief in the absolute harmlessness and perfect efficaciousness of this method. Much time and trouble are required thus to obtain the dilatation of all the vesicles, and sometimes it is not obtained at all; sometimes, too, subpleural emphysema is induced, which never occurs with the spirophore.—M. Cohn, in reference to the spirophore, read some remarks on asphyxia. His experiments had shown him that asphyxia is produced rather more quickly in the water than in cases of occlusion of the air-passages. The time necessary for asphyxia is longer in the larger animals than in small ones; the horse and the ox die at the end of five minutes, the dog and the rabbit in from three to four. At the moment when the respiratory and general movements cease, when immobility of the limbs, insensibility of the skin, and dilatation of the pupils supervene, death is only apparent. A period of from one to three minutes, during which the movements of the heart continue, separates apparent from definitive death, which is marked by the cessation of the cardiac systole. During this intermediate period, some movements of the costal walls, some rudiments of respiratory efforts which may speedily reanimate the asphyxiated patient, are perceived. It is during this transition period, while the heart-movements continue, that artificial respiration is useful. When the ventricles no longer contract it does not succeed in reanimating the heart, although the auricles beat for a shorter or longer space of time. So soon as the movements of the heart are arrested, or are no longer capable of propelling blood into the lung, artificial respiration is powerless; it is, therefore, impossible to reanimate asphyxiated persons long after apparent death. When once the circulation is stopped, there is no hope, and it stops from half a minute to one minute and a half after the suspension of the respiratory movements.

Artificial Vagina.—M. Léon Lefort read an interesting case of the formation of an artificial vagina without having recourse to a cutting instrument, but by the help of a slow and gradual sloughing, obtained by the prolonged use of the continuous current.

August 8. *Complete Extirpation of the Os Calcis.*—M. Ollier read a paper on the complete extirpation of the os calcis by the subperiosteal method. The conclusions of the paper were as follows. Total ablation of the os calcis, performed on young subjects by the subperiosteal method, is followed by the regeneration of the removed bone, a regeneration sufficient to preserve the protuberance of the heel, and the configuration of the plantar arch. The form of the new bone is determined by the form of the retained periosteal sheath; ossification may continue long after the cure of the wound, under the influence of the pressure and the friction occasioned by the use of the foot, at the same time the functions of the foot become re-established according to the normal

type. Those who have undergone the operation walk without support or instruments; they can attempt exercises which would be impossible unless the integrity of the skeleton of the foot were reconstituted; thus they can walk on tiptoe, on the heel, with the point of the foot raised up, and, what is crucial, stand on the toes of the foot operated on, with the other foot in the air. In the comparison of facts, the cases of total necrosis of the os calcis ought to be set aside, and distinguished from the regular subperiosteal operations, in which the surgeon has to detach from the bone a periosteum which is still adherent. In the case of necrosis there is only to extract an already isolated sequestrum, the ossification of the periosteum has already been able to commence all round, and the operation, a simple and easy one, will be attended by excellent results, nature having already done what the surgeon is obliged to do in cases of phlegmonous osteitis or caries, when the bone is still living. Though rarely indicated relatively to the frequency of osteitis of the calcaneum, extirpation finds its indication in the total inflammation of this bone and the extension of this inflammation to the neighbouring articulations, but deep-seated change in the contiguous bones is a contraindication to the operation. Amputation, unless the patient be young, is then preferable. Trephining, cauterisation of the interior of the bone, gouging, or extraction of the central sequestra, suffice in the majority of cases of osteitis affecting the os calcis. In the adult the impossibility of obtaining a regeneration of the bone, sufficient to re-establish the form of the foot, makes the application of the subperiosteal method also equally necessary. By leaving the tendo Achillis in continuity with the periosteal sheath, this will act on the skeleton of the foot like a prolonged tendon, and will preserve a part of the action of the biceps.

Cerebral Topography.—M. Broca read a memoir on cerebral topography, and on some points in the history of the convulsions. It was Gratiolet who first endeavoured to determine anatomically the relations of the cerebral lobes with the cranial walls. It is thus that he thought he discovered that the fissure of Rolando coincided with the coronal suture; in other words, that the frontal lobe of the brain corresponded exactly with the osteologic frontal lobe. Such, however, is not the case, and M. Broca's researches have shown him that the fissure of Rolando ought to be placed at the back of the coronal fissure. These topographic notes are very useful; it is important to know what part of the brain corresponds exactly with a penetrating wound or a depression of any given point of the cranium.

August 16. *The Spirophore.*—M. Depaul resumed the question of the asphyxia of new-born infants and the spirophore. It has the disadvantage of removing the child from under the eyes of the medical attendant, who ought to be constantly examining it; warm baths are impossible with the spirophore, as well as frictions of the limbs, the soles of the feet, etc. Heat is above all things indispensable to a new-born infant, more especially if it be prematurely born.

Decortication of Elephantiasis Noses, and its Definitive Results as regards the Form of the Organ.—M. Ollier read a communication on this operation, which preserves the cartilaginous skeleton of the nose intact, and removes the hypertrophied skin only. The wound is allowed to heal by granulation, and the cicatricial retraction, far from being trouble-

some, compensates the hypertrophy of the cartilages which always accompanies elephantiasis. Decortication may be performed with the bistoury, or the actual cautery, or by a mixed method. The actual cautery is very useful, especially in the vascular regions, where ligatures are uncertain. Every attempt at autoplasty to furnish a fresh covering for the cartilaginous skeleton is useless; at the utmost, recourse may be had to cutaneous grafts; not epidermic, but the large dermic grafts recommended by the author.

ACADEMY OF SCIENCES IN PARIS.

July 3. *The Blood in Anæmia*.—M. Hayem communicated his researches on the colour of the blood in anæmic persons. He had formed a scale of different tints, and he remarked that the variations of the colouring power are not in direct relation with the variations of the number of red corpuscles. On the other hand, his researches had shown him that in relation to the colouring power of the venous blood in a healthy man, the colouring power of the anæmic blood may oscillate between one-fifteenth and one-eighth.

July 10. *Tetanus*.—MM. Morat and Toussaint communicated their researches on the electric state of the muscles during artificial tetanus. All tetanus induced by a relatively unfrequent but constant number of excitations, if prolonged for a certain time, will present three phases. In the first phase the abrupt jerks of the inductor tetanus, which the graphic process shows already fused, are in reality accompanied by accentuated oscillations of the negative variations (induced tetanus); in the second phase, the fusion of the jerks becomes more and more perfect (gradual fall of the induced tetanus); third phase, the component jerks of the tetanus becoming more and more prolonged, the electric oscillations become attenuated, so as no longer to induce reactions in the galvanoscopic *patte* (cessation of the induced tetanus). By bearing in mind the modifications of the electric condition of the muscles, we can distinguish two types in artificial tetanus; one in which the jerks are fused with sufficient perfection to be almost invisible in the muscular tracing, but in which the value of the negative variation nevertheless undergoes oscillations at every jerk capable of inducing a secondary tetanus; this type may be considered as a yet imperfect tetanus. In the other type, not only are the jerks fused, but the negative variation is brought to an almost constant value; this is perfect tetanus, that which the indications of the galvanoscopic *patte* show us to be similar to voluntary contraction.

Fermentation of the Urine.—Dr. Charlton Bastian communicated the following memoir with reference to the influence of the physico-chemical forces. 'In the autumn of 1876, I ascertained that normal and acid urine rendered sterile by boiling might become fertile in two or three days when it was accurately saturated with potash with any other contamination, and after having been exposed to a high temperature. It is impossible for me to give in this extract from my memoir the details of my experiments; but I may say that I took the most minute precautions to avoid in my trials the influence of germs which might have been in the potash or on the sides of the vessels which I used. I also most carefully eliminated all the germs which might have been deposited by the air. As to the influence of

oxygen in the fermentation of urine, I ascertained it by submitting the urine (rendered sterile) neutralised by potash, to the action of an electric current, by means of platinum electrodes, which I had previously placed in the flasks containing the urine. In these experiments, as in the preceding ones, all precautions were taken to eliminate the atmospheric germs. The results of these experiments were very remarkable. Under the combined influence of the potash, the oxygen, and the temperature of 122° Fahrenheit (50° Centigrade), the sterile urine fermented rapidly and was filled with bacteria in from seven to twelve hours; that is to say, in a much shorter time than would have been necessary to cause fermentation in normal urine exposed to the air during the summer. It therefore results from the experiments which I have just analysed that the fermentation of urine is absolutely independent of the germs which may exist in the air.'

July 17. *Fermentation of the Urine*.—M. Pasteur contested the assertions made by Dr. Bastian on the fermentation of urine. The experiments of this writer, he said, are exact; but he cannot draw positive conclusions from them, because he has employed a watery solution of potash, and the water of that solution might have contained the germs of bacteria.

Fuchsine in Wines.—M. Husson communicated a memoir on the search for and the quantitative determination of fuchsine and arsenic in wines artificially coloured by fuchsine. Wines to which a little ammonia is added become of a dirty green tint, and a thread of white wool steeped in this mixture becomes discoloured by acetic acid if the wine be natural, and of a pink colour if it contain fuchsine. In order to determine the amount of the arsenic, the gaseous current which escapes from Marsh's battery is introduced into a titrated solution of iodine. Fuchsine seems to have a toxic effect on the lungs.

Anæmia.—M. Hayem read a third note on the blood in anæmia. In the adult in good health the blood contains about 5,500,000 red corpuscles to the cubic millimetre. In serious cases of anæmia this number may fall as low as 1,000,000. But in the slighter kinds of anæmia this or a greater number may be the normal standard. The best way of ascertaining the degree of anæmia is to verify the colouring power of the blood. For this purpose M. Hayem has formed a scale of tints.

Faradisation of the Brain.—M. Bochefontaine communicated a note on some phenomena determined by the faradisation of the grey cortex. 1. By means of the mercurial kymographion, it is ascertained that the faradisation of the points called motor centres of the limbs ordinarily produces a rise of from 14 to 16 centimètres of the blood-pressure in the carotids. At the same time the cardiac pulsations are slackened. Sometimes, under the influence of a single excitation, alternate accelerations and slackenings of the pulse are observed, and the medium tension is seen to undergo oscillations, whilst remaining higher than before faradisation. It is known that pressure also rises, and that the pulse is accelerated when the two vago-sympathetic nerves of the neck are cut. If the gyrus then be faradised the intra-arterial tension still increases, but the cardiac systoles are slackened. In several experiments, the section of the two pneumogastric nerves alone between the superior cervical ganglion and the base of the cranium, modified the effects of faradisation of the brain. The blood-pressure, instead of increasing at

the moment of this faradisation, is lowered from four to five centimètres; at the same time the pulse has become slower. 2. It is known that faradisation of the sigmoid gyrus brings on a considerable and immediate dilatation of the pupil. This faradisation, in an animal of which the spinal marrow has been divided transversely, brings on rapid dilatation of the pupil. Now, in this experiment, the excitation has not been able to follow the cervical cord of the sympathetic; it is probable that it has reached the isthmus of the encephalon whence it has been conducted to the ophthalmic ganglion of each side by sympathetic nerve-fibres, springing from that portion of the encephalon. 3. Faradisation of the brain brings on excessive secretion from the submaxillary and parotid glands, increasing the quantity of saliva secreted by glands tenfold. This fact may be utilised in physiology, in order to collect parotid saliva. 4. The stomach and the intestines are influenced by the stimulation of the limb-centres. The pyloric portion of the stomach contracts forcibly for an instant, then its peristaltic and antiperistaltic movements are either slackened or suspended. The intestinal walls contract in an irregular manner. 5. The bladder contracts, and more or less completely expels the urine which it contains. 6. The spleen becomes forcibly contracted, so as to diminish its bulk by one third. 7. If cannulæ be placed in the ductus choledochus, and in the pancreatic duct, as well as in Wharton's and Stenson's ducts, it is seen that the bile and the pancreatic fluid cease to flow when the faradic current is made to pass through the region of the sigmoid gyrus, whilst the submaxillary and parotid glands secrete abundantly. All these facts concur to show that faradisation of the points called motor centres of the limbs acts on the various apparatus of organic life.

July 24. *Pemphigus*.—M. Vulpian read a note by M. J. Déjérine on alteration of the peripheric ends of the cutaneous nerves in a case of eruption of bullæ of pemphigus. In a woman suffering from general paralysis with an eruption of pemphigus, diffused meningo-encephalitis and a sclerosis of the lateral cords along the whole length of the medulla, were found.

Dressing of Wounds.—M. Larrey presented, from Dr. Minich, of Venice, a work on the antiseptic treatment of wounds and on a new method of dressing by sulphite of soda. This substance is alleged to be superior to the other antiseptics, and is sold at a more moderate price.

The Fermentation of Urine.—Dr. Bastian replied to the objections of M. Pasteur respecting his experiments on the fermentation of urine. He declared that the watery solution of potash can only fertilise urine made sterile, in a proportion corresponding to the acidity and the exact quantity of liquid submitted to experiment. Besides this, both fresh and acid urine ferment under the influence of the temperature of 50° without the addition of potash.

REVIEWS.

Lectures on the Comparative Anatomy of the Placenta. First Series. By WILLIAM TURNER, M.B. Lond., Professor of Anatomy in the University of Edinburgh. With Illustrations in Chromo-Lithography. Edinburgh: A. and C. Black, 1876.

These lectures, which constitute the first part of Professor Turner's researches on the placenta in the higher mammals, were delivered by him last year at the Royal College of Surgeons in London.

Professor Turner prefaces his observations on the structure of the three groups of placenta—the diffuse, the polycotyledonary, and the zonary—by some remarks on the structure of the unimpregnated uterine mucous membrane, which is the seat of the developmental processes in the formation of the maternal or glandular portion of the placenta, and points out the absence of the utricular glands in this membrane until probably the stage of sexual maturity. Under the head of diffused placenta, Professor Turner has very fully described the placenta in the pig, the mare, and the cetacea. Professor Turner has found patches of chorion at each pole bare of villi in all three, and also stellate non-villous surface, nearly of the size of a crown-piece, and with several bare lines radiating from it opposite the os uteri, the arrangement corresponding very closely with that just described in the chorion of the mare in the same locality. These large radiating bare spots in the mare and cetacean are exaggerated representations of the small radiating spots, so abundantly distributed over the chorion of the pig.

In the two specimens of placenta in the mare which Professor Turner has examined, the chorion was studded with villi, except at the os uteri internum and opposite the Fallopian orifices, where it presented bare patches. These were placenta of advanced stages. Professor Ercolani, in his lectures on 'La porzione glandulare o materna della placenta,' describes the same appearances at the tenth week; he says, 'the whole external superficies of the chorion at the tenth week is studded thickly with villi, except at the os internum and orifices of the Fallopian tubes, where the development of the villi gradually disappears as one travels from the central portion towards the extremity of the uterine horn, or towards the internal aperture of the neck of the uterus.'

In the order Ruminantia, where the multiple or polycotyledonary form of placenta is found, the placenta in the well-advanced gravid uteri of both the sheep and cow are most minutely described; and the crypts in which the foetal villi are lodged are shown to be interglandular, as in the diffused placenta, and to be new structures formed during pregnancy by hypertrophy and unfolding of the interglandular part of the mucous membrane.

The description of the single or zonary placenta is illustrated by coloured plates, chiefly from microscopic drawings by Dr. J. C. Ewart. In this section the placenta of the carnivora, pinnepeia, and the hyrax, the placenta of which Professor Turner shows to agree with that of felis, not only in form and structure but in the large size of the sac of the allantois, differing, however, in the early disappearance of the umbilical vesicle.

Professor Turner supplements this portion of his lectures with a section on the 'General Morphology of the Diffused, the Polycotyledonary, and the Zonary Placenta.' He reserves until the concluding course of his lectures the consideration of the question, how far the modifications in the form and structure of the placenta may be taken as affording a sound basis for the classification of the placental mammals, and confines himself to the deciduate or non-deciduate character of the placenta described in this series. From observations recently recorded by

him on the shed membranes of the sheep and cow, at the Royal Society of Edinburgh, Professor Turner is of opinion that polycotyledonary placenta is not, as is usually supposed, non-deciduate, for he has seen quantities of maternal epithelial cells intermingled with the villi of the foetal cotyledons. These are Mr. Turner's words on this point. 'In a few instances I saw groups of such cells in immediate contact with the terminal villi, as if they, in being drawn out of the pits in the maternal cotyledon, had pulled an envelope of epithelial cells along with them.' He is therefore of opinion that the foetal cotyledons carry away with them, during the act of parturition, a portion of the maternal structure; so that in these animals, and presumably in other ruminants, the placenta is deciduate.

In the physiological remarks with which he concludes these most interesting lectures, Professor Turner states that he believes that the utricular glands continue to pour out their secretion throughout pregnancy; in which belief he differs from Professor Ercolani, who believes that their secretion ceases when the secretion in the crypts commences.

As Professor Turner's views on foetal nutrition are new, it is as well to give his own words. 'As there are two sets of secreting structures in the gravid maternal mucosa, the glands and the crypts, each of which has in relation to it a definite and usually distinct surface of the chorion, it may be a matter for consideration how far these secreting organs perform similar or different functions in foetal nutrition. . . . In the mucous coat the pre-existing utricular glands are enlarged, and in addition multitudes of crypts are developed, in which secretions are produced capable of nourishing the foetus during its intra-uterine life, so that the maternal placenta is a great secreting organ. If this view of the function of the maternal placenta be admitted, then the current doctrine that the nutrition of the foetus is provided for by a simple percolation or diffusion of materials through the walls of the vessels from the maternal blood to the foetal blood can no longer be accepted.' With regard to the interchange of gases in the placenta, he says, 'The interposition of a layer of cells, possessing some thickness, on the surface of the maternal placenta, between the two systems of vessels, whether these cells be regarded as secreting or not, necessarily throws a mechanical difficulty in the way of the ready passage of gases from the one set of vessels to the other, and might be used as an argument against the theory of intra-uterine respiration.' Professor Turner is therefore of opinion that the problems of nutrition and respiration in the foetus are not satisfactorily solved. FANCOURT BARNES, M.B.

A Practical Treatise on Urinary and Renal Diseases, including Urinary Deposits. Illustrated by numerous cases and engravings. By WILLIAM ROBERTS, M.D., F.R.C.P. Lond., Physician to the Manchester Royal Infirmary; Professor of Medicine in the Owens College, Manchester. Third Edition, revised and enlarged. Pp. 631. London: Smith, Elder, & Co. 1876.

It is too late in the day to write an ordinary review of this book. A third edition of a work of this size makes the author quite independent of all carping and petty criticism. Dr. Roberts has not only produced a good book, but he has filled a manifest blank in medical literature. Before the publication of his first edition, practitioners had Vogel and

Neubauer, Prout, and Golding Bird, Lionel Beale, and a host of minor works on the kidney and urinary diseases, together with hundreds of scattered papers of more or less value in English and foreign medical journals and year-books. No one of these volumes was exactly what a busy practical man wanted. One was too chemical; and if he wanted to learn how to test for sugar or albumen, or other normal or abnormal constituents of urine, he was offered a variety of processes, an *embarras de richesses*, which puzzled him, because he did not know which to choose. Add to this that many of the descriptions, especially in German works, were none too clear, and we cannot wonder if the plain practical man felt puzzled. Another work on the same subject was almost entirely microscopic, and perhaps either his eyesight or his early training disqualified him from pursuing this mode of inquiry with much zeal. As to collecting and collating the multifarious literature scattered in journals and reports, neither his time nor the public or private libraries to which he had access enabled him even to attempt such a labour of Hercules. To such a man, to the average intelligent but hard-worked practitioner, Dr. Roberts' book is a perfect God-send. It contains directions for the analysis of urine in clear and intelligible terms. It does not demand any great amount of apparatus. There is a good deal about the microscope and its revelations *quoad* urine, and the whole is made intelligible by actual cases. More than this, all the best English and foreign literature has been laid under contribution by Dr. Roberts, and the result is that the average practitioner who masters the contents of this book is placed 'alongside' of all that is really known of the kidney and its diseases. The second edition was an improvement on the first. The third is an improvement on both. Amongst the changes in this edition are an account of Russell's and West's method of estimating urea, of Dr. Lewis's discovery of the *filaria sanguinis hominis* (with figures) and of its connection with chylous urine; then a brief notice of the views of Gull and Sutton, and of Dr. Dickinson's researches on the morbid anatomy of diabetes. The author's new mode of estimating albumen by dilution is also described. Of this we can only say that, although highly ingenious, we doubt if it will ever become popular. The author estimates the necessary time for the process at from ten to twenty minutes. But in ordinary hands it is more likely to take thirty or forty minutes—a length of time which must prevent the clinical use of any method. If an example were wanted, Liebig's process for urea testing would supply us with one. Excellent and accurate as it doubtless is, it is seldom employed, merely because the time required is too long.

If we were disposed to be a little hypercritical, we should point out that, whilst Dr. Roberts professes to confine himself to methods and processes which are practical and generally admitted, and for this reason dismisses a variety of tests for albumen and sugar with the curtest of notices, he yet enters at some length into the views of Schunk on urinary pigments, which are certainly at the present moment not generally admitted by chemists, and still a debatable ground. This, however, is a matter of small moment. It does, however, seem to us to be a matter of some importance that Dr. Roberts has not alluded (or at all events only in the most cursory manner) to the great importance of using clean test-tubes in testing for albumen. Very few days pass

by without our finding some student or some practitioner overlooking the existence of albumen in urine, because he or they have used test-tubes which were not cleansed from nitric acid. We owe the discovery of this source of fallacy, if we mistake not, to Dr. Brown-Séquard. We think, too, that Dr. Roberts has not made it quite clear that albumen in the urine is very often quite distinct from chronic kidney-disease, as its presence may be caused by an excess of azotised or albuminous food, or by leucorrhœal and other purulent discharges, or by temporary congestion of the kidneys. Again, in the section on diabetes insipidus, Dr. Roberts scarcely mentions the gravity of the prognosis. We believe that Dr. Ramskill, who has seen a large number of these cases, says that they nearly all terminate in more or less sudden death. One striking instance of this kind is recalled to our memory. A young woman, aged about twenty-three, was under treatment as an out-patient of the London Hospital for diabetes insipidus. Dr. Woodman had charge of this case. The daily secretion of urine was about eight or nine pints. Its specific gravity was 1.002. She had slightly improved whilst taking quinine when she sprained her ankle, and was taken into the surgical wards of the London Hospital. No mention was made of her previous complaint, and in a week or so she was discharged as cured, the chairman of the House Committee congratulating her on her blooming appearance. As she was leaving the hospital, she died on the very threshold or doorstep. At the *post mortem* examination no adequate cause of death was discovered. As, however, the pathologist was in ignorance of her previous history, it would seem that the fourth ventricle and other parts of the nervous system were not very minutely examined. Other cases of very similar nature are known to the reviewer. These, however, are but very minor blemishes in a book which, in our opinion, is one of the very best which has ever issued from the press in modern times. The publishers have done their part well; the book has been adorned with a coloured plate of Vogel's colour-standards of the urine, and with eighty or more illustrations on wood. We shall perhaps best show the style and practical character of the work by extracting that part which treats of 'Russell and West's Modification of Davy's Process for the Estimation of Urea.' Dr. Roberts writes as follows.

'The principle of this method depends on the decomposition of urea by the hypochlorites and hypobromites. The amount of urea is determined by measuring the volume of nitrogen evolved.

'A solution is prepared by dissolving 100 grammes of solid caustic soda in 250 cc. of water, and adding 25 cc. of bromine. The apparatus constructed by Dr. Russell and Mr. West for the performance of the analysis is both compact and cheap. [Cetti, Brook Street, Holborn, London, price 8s. 6d.] But it is not so convenient and accurate to work with as that devised by Mr. Apjohn. Mr. Apjohn's apparatus consists of:—

'1. A glass measuring tube of about a foot in length, drawn out at the end which will be uppermost when the tube is used like a Mohr's burette, and subdivided into thirty parts of equal capacity, the aggregate volume of which is 55 cc.

'2. A small, wide-mouthed, glass bottle of about 60 cc. capacity.

'3. A short test-tube of 10 cc. capacity, and of such height that when introduced into the gas

bottle it will stand within it in a slightly inclined position. The following are the arrangements for combining the apparatus and working an experiment. [Here follows a woodcut.] The graduated tube, held in a clamp attached to a retort stand, is depressed into a glass cylinder, nearly filled with water, until the zero mark, which is near the upper end, exactly coincides with the surface of the water. 15 cc. of the hypobromite solution (100 grammes of NaHO, 250 cc. of water, 25 cc. of bromine) having been poured into the bottle, the test-tube containing the urine is introduced by means of a forceps, care being taken that none of its contents shall spill into the hypobromite. The flask is now closed with a very accurately fitting India-rubber stopper, perforated with a hole, in which is inserted a short piece of glass tubing, open at both ends, and is then connected with the measuring-tube by means of a piece of elastic tubing. It is now inclined so as to allow the urine to mix with the hypobromite. Effervescence at once commences, and as it proceeds the measuring-tube is gradually raised so as to relieve the disengaged nitrogen from the hydrostatic pressure. The flask is shaken a few times, and when the reaction is completely over, the apparatus is left for a few minutes, until it has acquired the temperature of the room in which the experiment is performed. Another exact levelling of the measuring-tube is made, and the number of the division corresponding to the volume of the developed nitrogen is read off. The tube is so graduated that when 5 cc. of urine are operated on, each division corresponds to 0.1 per cent. of urea, or 0.44 grain per fluid ounce of the British Pharmacopœia. An easy calculation from these data gives the daily discharge of urea. Suppose 45 ounces of urine are voided in the 24 hours, and that 5 cc. of this evolves 20 measures of nitrogen with the hypobromite solution, then $0.44 \times 20 \times 45 = 396$. The daily discharge of urea was 396 grains.

'I have carefully tested this method, and have found it easy, accurate, and speedy.'

It should have been mentioned that the hypobromite solution will not keep long, and should from time to time be tested with a standard solution of urea.

Dr. Roberts's work is accompanied with a good index, and every chapter is preceded by bibliographic references of extreme value and interest.

Studien in der Anatomie des Nervensystems und des Bindegewebes. Von AXEL KEY und GUSTAF RETZIUS. Stockholm: 1876.

Studies in the Anatomy of the Nervous System and of the Connective Tissue. By AXEL KEY and GUSTAF RETZIUS of Stockholm.

These researches began in 1869, and have been continuously carried on. Their origin was the object of determining the connection between the sub-arachnoid spaces of the brain and cord. Injections of the spinal subarachnoid space caused not only injection of that of the brain, but also of the ventricles, and of the inner lymphatics of the brain and cord; in addition, there was a discharge of the serous fluid of these spaces towards the vascular system through the Pacchionian bodies, and these spaces were found to be in direct connection with the lymphatic system of the body and with the lymphatics of the perceptive organs and of the peripheral

nervous system. The space between the dura mater and the arachnoid was found in the cerebral organs to be quite separated from the subarachnoid and internal lymphatic spaces, and only to be connected with them peripherally, since this space has an outflow to the system of blood-vessels through the Pacchionian bodies, and is connected with the peripheral lymphatic system and with that of the higher perceptive senses as with those of the peripheral nerves. By injecting the peripheral nerves they not only found the lymph-canals, but were led to a complete investigation of the structure of the nervous system in general, and also of the connective tissue. In the membranes of the brain and cord they found types of the cellular and of the firm fibrous tissue; in the peripheral nerves they found a lamellar form, besides various others. Much trouble has been bestowed on the plates, and the text is given in German. The first part of the work is now published; the second part will appear in the present year. The first part contains an account of the membranes and serous spaces of the brain and cord, and of the subdural space, the subarachnoid space, and the general arrangement of the pia mater; the open connection of the brain-ventricles with the subarachnoid spaces; the general and special histology of the pia and of the dura mater, the Pacchionian bodies, the sheath and the sheath-spaces of the optic nerve and their connection with the serous spaces of the brain, the internal constitution and the canals of the optic, the lamina cribrosa, the optic papillæ, the connections of the sheath-spaces of the auditory nerve and of the labyrinth with the serous spaces of the central nervous system, and the lymph-canals of the nasal mucous membrane as connected with the serous spaces of the central nervous system. The second part contains the construction of the perivascular system of the cerebro-spinal and sympathetic ganglia in addition to the general structure of connective tissue. The price of the first half (to be obtained from Messrs. Williams and Norgate, Covent Garden) is 8s. The first part contains 217 pages. The plates are beautifully worked up, and eminently merit the attention of histologists.

In order to afford a better idea of the way in which the work has been carried out we give a brief summary of the text accompanying the plates on the lymphatic canals of the nasal mucous membrane in their connection with the serous spaces of the central nervous system. Schwalbe succeeded in injecting from the subdural space of the brain lymph-vessels in the nasal mucous membrane. Key and Retzius, by injecting the subarachnoid spaces of the cord and brain, achieved a filling of the perineural sheath of the nerves of the nasal mucous membrane, and between these branches a net of vessels which was separated from the blood-vessels, and corresponded with the lymph-canals. Michel had already arrived at a somewhat similar result.

When they allowed a coloured fluid (Richardson's blue) under continued mild pressure, to flow into the subarachnoid spaces of a recently killed dog or rabbit, the canals and network of vessels in the nasal mucous membrane were more or less filled. At first were seen long cylinder-tubes, more or less parallel, radiating from the lamina cribrosa, being, in fact, an injection of the olfactory twigs. The extent was more or less, according to circumstances. It frequently happened that in addition injection reached a network of fine anastomosing passages, which, found chiefly in the vicinity of the lamina cribrosa,

pervaded the mucous membrane, forming long meshes lying between and parallel to the nerve-twigs, and crossing them; at times this network extended to the external nasal orifices, and might be found occasionally in connection with an injection of the frontal sinuses. It became a question whether this network belonged to the lymphatic or to the venous system, but they proved that the vessels injected from the subarachnoid spaces were quite separate from the blood-vessels. On complete filling of the blood-vessels of the nasal membrane, arteries, capillaries, and veins, the network injected from the subarachnoid space was found to be quite independent. Hence it was clearly lymphatic in nature, and these lymphatics grouped themselves in stems, which finally ended in lymph-glands of the neck. That the lymph-vessels can be injected quite independently from the perineural ones, simply proves that they can be quite filled without any filling of the perineural nerve-sheaths, just as these can be without filling the lymphatics. Thus the lymph-vessels must, in the greater part, stand in absolute connection with the serous cavities. Similar results were obtained by the asphalt-chloroform injection of Ludwig. In addition, they show a system of juice-canals (*Saftbahnen*), which are really connected with the lymphatics, such as Lovén has recently shown in the stomach. They conclude that an injection under gentle pressure of the subarachnoid of the brain does, by the medium of the lymph-canals of the nasal mucous membrane, fill the juice-canals of this membrane; and, further, that an efflux through special canals in the epithelium on the surface of the last occurs, consequently demonstrating a connection of the subarachnoid spaces of the central nervous system with the outer world. The results were not quite so complete in man, owing to the greater density and resistance of the Pacchionian bodies.

T. CLAYE SHAW, M.D.

Atlas of Skin-Diseases. By LOUIS A. DUHRING, M.D., Professor of Skin Diseases in the University of Pennsylvania; Physician to the Dispensary for Skin Diseases, Philadelphia. Part I. Philadelphia: J. B. Lippincott and Co. 1876.

In a short preface to this *Atlas*, the author declares his opinion that there is an urgent need for such a work in American medical literature; and indeed we believe that this is the first effort of the kind that has been made in the United States to illustrate this branch of pathology.

In Europe of late years much has certainly been done in this direction; for, not to mention the excellent collection of coloured wax, *papier maché*, and plaster of Paris casts to be seen in various continental museums, and now happily being formed at the Royal College of Surgeons and at several of the large schools in London, we have the grand '*Atlas of Hebra*,' the plates issued occasionally by the New Sydenham Society, and, lastly, the production in modern form of Bateman's '*Atlas*,' by Dr. Tilbury Fox.

We confess that we attach importance to these demonstrative methods, believing that faithfully executed and artistic drawings of skin-diseases afford means for ready and accurate diagnosis in many instances. We have ourselves been enabled to recognise certain rare forms of skin-affection by such means.

In this, the first fasciculus, Dr. Duhring, who,

we may mention, is one of the most accomplished and diligent cultivators of dermatology in any country, has presented us with four plates. On the next page there follows a description of the disorder depicted, with a concise account of the case from which the drawing was made. Points assisting to make the diagnosis and the treatment are also given.

The first plate is that of a case of Eczema erythematosum. This form of eczema is amongst the rarest in this country, though not uncommon in America. Milder forms of it are, however, met with not unfrequently, and are perhaps mostly confounded with forms of erythema.

The second plate is one of Psoriasis, and is admirably executed, having been drawn from a typical example of the benign or non-syphilitic form. Under the heading of treatment, we observe that Dr. Duhring does not appear to lay sufficient stress upon the value of hydrotherapeutic medication, internal or external, in this disorder. This is a plan which, we believe, is too much neglected in these cases.

Drawing number three illustrates Lupus erythematosus. The implication of the sebaceous structures is perhaps less well depicted than might be, but we imagine the subject is as 'rebellious' to the artist's pencil as the author declares the disorder to be to treatment. We are inclined to prefer long-continued administration of cod-liver oil and the occasional smart use of nitrate of silver locally in these cases, with a free allowance of a bismuth paste in the intervals.

Plate four illustrates a Pustular Syphiloderm, which is sufficiently characteristic, and the history and progress of the case which furnished the drawing are carefully recorded.

We think highly of Dr. Duhring's plates and of his text. The latter is printed on beautiful paper and in clear type. The author gives distinct evidence of honest and accurate work, and of thorough knowledge of his subject. The student could well follow no safer guide into the perplexities of cutaneous medicine than the present Philadelphia professor of that branch.

An Elementary Treatise on Diseases of the Skin.

By HENRY G. PIFFARD, A.M., M.D. Macmillan and Co. London and New York. 1876.

Dr. Piffard gives evidence in this volume of one essential requisite in an author, a thorough acquaintance, namely, with the contemporary literature of his subject. He has not only assimilated the views of the classical German, French, and English dermatologists, but has lost nothing that has been contributed to periodical publications up to a very recent period. The advantage to the reader is in some instances considerable, as for example, in the good account of the different opinions held regarding the parasitic origin of Alopecia Areata. The book does not carry the stamp of originality, but in an elementary treatise that is not necessarily a drawback.

Like all recent authors who have written in English on skin-diseases, Dr. Piffard has drawn largely on the work of Professor Hebra, whilst at the same time a tribute is paid to the French school by the adoption of the *dartres* theory. The classification of skin-diseases is a task attempted afresh by each successive author, and we are not surprised to observe that Dr. Piffard proposes his own. Those who are interested in such matters may like to know

that he divides them into : 1. Diathetic Affections ; 2. General Non-Diathetic Affections ; 3. Reflex Affections ; 4. Local Affections ; 5. Affections of Uncertain Nature.

A laboured attempt to explain the origin of the *dartres* of the French (named the *Rheumides* by our author) by faulty action of the kidneys fails to convince, because it rests solely on some theoretical assumptions, not always very clearly expressed and unsupported by direct evidence.

The chapters on some of the rarer skin-diseases which have been described by Hebra although short are clear. Dr. Piffard has avoided the pitfalls into which some English writers have lately tripped by giving in essence Hebra's own description of lichen ruber, lichen scrophulosorum, prurigo, chloasma, and some allied diseases. Adopting this nomenclature he has not confused it by an introduction of the term morphæa, which is not to be found in the book.

The volume is well got up, and the author's style is usually simple and clear. It is abundantly illustrated by woodcuts from various sources which, however, do not add much to its value. Although not likely to become a standard work, it will be read with advantage by those who do not care to study more extensive treatises. Some of the chapters might have been shorter without diminishing its value.

Practitioners will find some useful hints in the sections devoted to treatment.

NEW INVENTIONS.

GLYCERIN SOAP.

In the combination of fatty matters with alkalies forming soap, the decomposition which ensues separates the fatty acids from the glycerin base, and the water containing the solution of alkali has a greater affinity for the glycerin than for the stearate, palmitate, and oleate of soda. It follows, therefore, that the small quantity of glycerin usually found in soaps of that description is so far diluted by admixture with the water, that its emollient properties are greatly weakened. In many diseases of the skin nothing has been found more efficacious than glycerin combined with alkali on the one hand, or with a weak acid, such as boracic, on the other. The first of these is strongly recommended by Dr. Liveing to be used in acne, the latter as a lotion for general use in eczema. In fact, throughout the whole of the formulæ appended to the notes on the treatment of skin-diseases by the eminent physician of Middlesex Hospital in charge of the cutaneous department, glycerin appears to be more relied on than any other medicine prescribed. The greatest improvement in combining glycerin with soap appears to be that adopted by the well-known German soap-maker, Gustav Boehm, of Offenbach. From an examination of his glycerin soap, it would seem that he has arrived at so perfect a means of retaining the glycerin free and undiluted, that while it is certified to contain over 22 per cent. of glycerin, there is only 19 per cent. of water combined with the fatty acids and alkali. Ordinary curd soap contains 33 per cent. of water, while cocoa-nut oil soap frequently contains as much as 75 per cent. of water ; and even the far-famed Naples soap contains more than 27 per cent. of moisture. The ordinary glycerin soaps of commerce are also sometimes compounded with glycerin

of inferior quality containing impurities which are anything but beneficial when applied to the skin. This defect is entirely obviated in Mr. Boehm's Glycerin Soap, by the purity of the ingredients and the method of manufacture. By manufacturing a soap with so little water, and afterwards purifying it thoroughly with alcohol, a soap of marvellous transparency is produced, in which the free and undiluted glycerin is available for all those medicinal purposes of external application for which glycerin is so strongly recommended.

HARPER'S PATENT STEAM DRAFT INHALER.

The advantages of inhalation in the treatment of many maladies connected with the throat and lungs are too well known to require enumeration. The simple effects obtained from the application of warmth to an inflamed surface, the relief of pain which it gives, and the diminution of inflammatory action which follows, are familiar to everyone. The plan of ordering a patient to employ a jug of warm water, or even one of the inhalers in common use for this purpose, is only partly satisfactory, as there is an insufficient supply of air in combination with the steam which is inhaled to allow of its being continued without fatigue for more than a few minutes. Harper's Inhaler entirely provides for this desideratum, and is in every respect far superior to any inhaler yet introduced to the profession. It enables the patient to inhale without the least fatigue for any period prescribed, a warm vapour containing more than 90 per cent. of pure air, the small quantity of steam being sufficient to give it proper moisture. The various remedies which are used in various conditions of the throat, as in diphtheria, bronchitis, etc., may be combined perfectly with the vapour and inhaled more completely than by any other method we are acquainted with, and may be brought into contact with the affected surface in the most effective manner.

MISCELLANY.

DR. SIMON, Professor of Surgery in Heidelberg, has lately died.

THE University of Upsala is making preparations for the celebration in September, of the four hundredth anniversary of its foundation.

PROFESSOR ALLEN THOMSON, of Glasgow, has been elected President of the British Association for the Advancement of Science for the year 1877.

A PROPOSAL by M. Clémenceau for the appropriation of an annual sum of 13,000 *francs* to the creation of a Chair of Mental Alienation and Diseases of the Nervous System in the Faculty of Medicine in Paris, has been adopted by the Chamber of Deputies.

DR. FRANCIS SIBSON, F.R.S., formerly Physician to St. Mary's Hospital, London, and a Vice-President of the British Medical Association, died suddenly in Geneva on the 7th instant. His loss will be regretted by a large circle of friends, by whom he was held in high esteem.

COMPLIMENTARY!—It is stated that Terra del Fuego has been traversed by Lieut. Masters, R.N., who has discovered that the natives believe in devils, and hold them to be the departed spirits of members of the medical profession. The main object of their religious ceremonies is to keep these devils at a distance from them.

ANKYLOSIS OF CERVICAL VERTEBRÆ.—In a letter to the *Philadelphia Medical and Surgical Reporter*, Dr. Farnsworth, of Clinton, Iowa, says that in the examination of some ancient mounds in that vicinity, some skeletons were found, very well preserved. The tibias were very flat. In several skeletons there was an ankylosis of the three or four cervical vertebræ below the atlas. Recently several graves of the modern Sioux were opened, who died from among the prisoners held at Davenport in 1862–3, taken after the raid made on the inhabitants of Minnesota in 1862. In one skeleton the tibias were flat, in another more nearly round; in one also the same complete ankylosis of the cervical vertebræ existed.

THE LATE PROFESSOR TRAUBE.—The following sketch of the life of this eminent physician is condensed from the *New York Medical Record* of May 13. Louis Traube was born January 12, 1818, in Ratibor. He studied in the Universities of Breslau, Vienna, and Berlin; was promoted in the last university in 1840, and took his State's examination the following year. During his ante-graduate years he was at one time a colleague of Du Bois-Reymond, Virchow, and Helmholtz. In Vienna he was a most diligent pupil of Rokitansky and Skoda, who, it may be said, gave him the first incentives to those anatomico-pathological investigations which developed ultimately into the use of the thermometer and temperature registration in medicine. For three years after his graduation he acted as assistant to a physician in Voigtland, where with unusual zeal he made the clinical study of diseases of the chest and abdomen his chief pursuit. In 1843 he instituted exercises in auscultation and percussion, collected about him many physicians and students, and freed the new method of exploration, by his accurate physiological and pathological investigations, of many errors. In 1848 he was made Privatdocent in the University of Berlin; in 1849, assistant to the clinique of Professor Schoenlein, which position he held for ten years. During this time he was assigned to the department of Diseases of the Chest in the Charité, which represented, as it were, an appendix to the Schoenlein-clinique, and gradually developed into a distinct, self-sustaining clinique. In 1868 he refused a call to the University of Heidelberg, as also later similar invitations to Breslau, Zurich, and Bonn. He remained an instructor in the University of Berlin until, in 1872, it saw fit to advance him to the position of Ordinary Professor,

in which office he died. Traube is known to the scientific world as the first one who utilised thermometry at the bedside. By his students he will be remembered for his definite diagnosis, accurate prognosis, and the simplicity of his presence. He was not only a remarkable practising physician, not only a clinical teacher of rare endowments, but also a man of exact scientific inquiry, and standing in the front ranks of reformers in medical, as distinguished from surgical, theories. Though still young, he has occupied for twenty years perhaps the highest position of any consulting practitioner of medicine in Berlin, in the opinion of the public. The second half of the decade, 1840–50, witnessed here a reform in which Traube played a prominent rôle. It arrayed itself, on the one hand, against formal, dry dogmatism, which was at home in most of the doctrines of the German universities, and against the ultraism of the *à priori* system of the natural philosophy school; and, on the other hand, no less against the experiments made under the leadership of Rokitansky, in Vienna, where, until then, no man had dared to express the conviction that pathological anatomy must be the groundwork, not only of medical science, but also of medical commerce; indeed, that it contributes all which goes to make medicine, as a science, positive and fundamental. The new Vienna School displayed a triumphant banner through all Germany; and, strange enough, it encountered harsh criticism from a few hitherto unknown young physicians of Berlin. A part of these young men pursued the studies of physics and physiology, as Helmholtz, DuBois-Reymond, and others; while Traube and Virchow devoted themselves to pathology, by experiment and clinical observation. In 1846 Traube's first work, 'Contributions to Experimental Pathology and Physiology,' was published. After a quarter of a century of work in the same direction, he found no occasion to change his early results. Virchow writes, at this early time, of the independent direction of his experimental study, and of his most accurate methodical investigation. Typhus and pneumonia he studied with the thermometer in his hand. He developed the various actions of digitalis, with which Schoenlein was so pleased that he encouraged the investigation by large uses of the drug in his clinique. As in diagnosis, so in therapeutics was Traube equally exact, and never tired in busying himself with details in treatment. Naturally enough, he was one of the most successful of teachers, and as a successful clinical instructor is he best known by most of the physicians who during the past twenty-five years have been graduated at this University.

EHRENBERG.—The following notice of the late distinguished naturalist, Ehrenberg, is taken from a letter of the Berlin correspondent of the *Boston Medical and Surgical Journal*. Christian Gottfried Ehrenberg was born in Delitzsch, April 19, 1795. At the age of twenty years he went to Leipsic to study theology. The inclination of his youth, however, was to medical studies, and he remained but half a year in Leipsic as a theological student. In 1817 he came to Berlin, and matriculated in the young university. To physiological chemistry he devoted most of his time; in 1818, while yet a student, he made a contribution to the systematic study of fungous growths. His inaugural dissertation was an effort in the same direction, its topic being *Sylvæ Micologicæ Berolinenses*. It displayed independent and bold thought, and added to the physiological knowledge of these Berlin growths; it gave its author the reputation of critic of the idea, then existing, of the transformation of inorganic substances into organic. A more extensive report of his investigations into the development of fungus and mould he communicated in the transactions of the Leopold Academy of Naturalists of Bonn, in 1820. In this same year, under the auspices of the Academy of Natural Sciences, Berlin, he made a scientific tour with Dr. Hemsich, a distinguished naturalist of Berlin. During an absence of six years the Libyan Desert, Middle Egypt, Syria, and Arabia were visited; the report of these researches was published under the title,

Natural History, Travels through North Africa and West Asia in the Years 1820-1825. Soon after his return he was made extraordinary professor in the Medical Faculty of the University of Berlin. In 1829 he was selected by Von Humboldt to accompany him on his researches in Siberia, more particularly in the Ural Mountains. The expedition was fitted out with a leader in nearly every department of natural science, and furnished with money without stint. The Russian Emperor prepared relays of horses, halting-places, and every possible convenience, so long as the expedition was in his domain. The results of the two years' investigations were published together, those of Ehrenberg appearing side by side with those of the then renowned Humboldt. Continuing investigation in the department of animal physiology, he published between 1828 and 1834, under the name of *Symbolæ Physicæ*, contributions to the anatomy and physiology of the lower animals. These were known respectively as *Symbolæ Physicæ Mammalium*, *Avium*, *Insectorum*, and *Animalium Evertetratorum*. In 1835 he published an article on Phosphorescence, interesting from a scientific stand-point, together with a review of the chronological development of this remarkable phenomenon, which he attributed to infusoria. Three years later, 'Infusoria as Perfect Organisms,' 'A Glance at the Deeper Life of Organic Nature,' was published by him. This work was not only rich in new materials, but contained a systematic review of all that was heretofore known of infusoria and radiata. Though devoted to a specialty from the character of the investigation, it was so comprehensive in its range as to win the consideration and position of a text-book. In 1839 he was promoted to an ordinary professorship. This year found him elected foreign member of several scientific societies, of which the Royal Society of England paid him the most distinguished honour. Among other distinctions given him at this time of his life was his election, in 1842, as one of the thirty knights of the order of the *Friedens Klasse*, accompanied by the decoration *pour la mérité* for science and art. One of his last contributions to scientific literature was the voluminous work on mineralogical formations by microscopic organisms under the title of 'Micro-Geology.' The decadence of Ehrenberg's life was marked by a series of personal griefs, the chief of which were the death of his wife and the gradual loss of sight by cataract. He lived but a few weeks after the successful removal of the cataract, and died in the infirmity of old age. His burial was imposing in the style of its celebration, and honoured by the character of the personages in attendance. The funeral cortege was headed by the 'gala-equipage' of the Emperor, and passed through a thickly-settled portion of the town out to the Marienkirchhof. Among the nearest mourners were the elder professors of the medical, natural science, and natural history faculties.

THE ITALIAN MEDICAL ASSOCIATION.—The following subjects are to be discussed in the various sections of this association, which will be held in Turin from the 18th to the 23rd inst. *Section of Physiology.* 1. The necessity of vivisection for the progress of medico-chirurgical science, and especially of physiology. 2. Is it useful to take account in physiology, as well as in pathology, of differences of temperament, habits, and individual constitutions? 3. The teaching of physiology to youth. 4. The graphic method and its applications to medicine. 5. The action of certain alkaloids on the heart and lungs. 6. The use of the semi-circular canals. 7. The introduction of drugs into the organism; their metamorphoses and elimination. *Section of Medicine.*—The transmission of sounds through the pleuritic fluids of different kinds. 2. The results obtained by the external use of cold water in the treatment of typhoid fever. 3. Aphasia: its causes, situation, and treatment. 4. The indications and contraindications of thoracentesis. 5. The results of chemical experience of new remedies—salicylic acid, jaborandi, eucalyptus, trimethylamin, nitrite of amyl, and sulphium Cyrenaicum. 6. Hydrate of choral in rheumatic and traumatic tetanus. 7. Paracentesis of the pericardium. 8. The therapeutic value of hypodermic in-

jections in general. *Section of Surgery.*—1. Transfusion of blood: its indications. 2. Median cystotomy: its special applications. 3. Digital compression, either alone or combined with mechanical pressure, in the treatment of aneurism. 4. Subperiosteal osteoclastic, and osteoplastic resections. 5. Phosphorus necrosis of the maxillæ: the means of preventing and curing it. 6. Lister's antiseptic surgery: its indications and contraindications. 7. The treatment of wounds. 8. The value of electro-chemical and electro-thermic treatment in practical surgery. *Section of Diseases of Children.* 1. The causes, prevention, and treatment of diphtheritic angina. 2. The indications and contraindications of tracheotomy in croup. 3. Rickets: schools for rickety children, and gymnastic education. 4. Scrofula: the advantages obtained by the institution of seaside hospitals in Italy. 5. Tubercular meningitis in children. 6. The best means of establishing, near the University, hospitals for the diseases of children. *Section of Syphilography.*—1. Prevention of syphilis. 2. Are lock hospitals best managed under the direction of the State, or under that of the Provinces and Communes? 3. Are there two varieties of syphilitic ulcer, or only one? 4. The various methods of treating constitutional syphilis. 5. Syphilitic diseases of the nervous system. 6. Vaccinal syphilis. 7. The pathological conditions in the various forms of syphilis, in relation to the treatment by mercury and by iodine. *Section of Ophthalmic Surgery.*—1. The efficacy of paracentesis of the cornea in various diseases of the eyes. 2. The value of electro-therapeutics in diseases of the eye. 3. The advantages to be obtained from hypodermic injections in diseases of the eye. 4. The cause of ocular tension. 5. The treatment to be preferred in the treatment of affections of the lacrymal passages. 6. How far can science act with advantage in desperate cases of blindness arising from disease of the iris and cornea? 7. The causes and the morbid processes which may produce atrophy of the optic nerves. 8. The value of surgical operative proceedings in conical cornea. *Section of Obstetrics and Gynecology.*—1. The most simple and efficacious means of establishing obstetrical and gynecological polyclinics in large cities. 2. In regard to the question of doctresses, would it not be useful and opportune to inquire whether the theoretical and practical medical instruction at present given to midwives is sufficient? 3. The etiology and prevention of abortion. 4. The causes of the puerperal process. 5. When the mother cannot suckle her child, what is the best means of nourishing it? 6. The present state of ovariectomy in Italy. *Section of Dermatopathology.*—1. The anatomical and clinical relations between lupus, cancer, and tubercle. 2. The local and constitutional value of dermatoses. 3. Anatomico-therapeutical study of dermatoses. 4. The relation between epithelial and papillary diseases. *Section of Hygiene and Public Medicine.* 1. The climate of Rome. 2. The present conditions of cremation. 3. The best means of opposing the increasing intemperance in the use of alcoholic liquors. 4. The ideal of a city formed on hygienic principles. 5. The means of overcoming and neutralising marsh miasm. 6. The reforms which most urgently require to be adopted for the hygiene of hospitals in Italy, the obstacles to carrying them into effect, and the means of removing them.

CRUELTY TO ANIMALS.—The Act passed at the close of the Session which occasioned so much discussion on the subject of vivisection, is to amend the law relating to cruelty to animals. It extends to the United Kingdom, and has immediate operation. The preamble recites that it is expedient to amend the law relating to cruelty to animals, which for medical, physiological, or other scientific purposes are subjected, when alive, to experiments calculated to inflict pain. The law, as amended, is contained in twenty-two sections, but whether it is so clearly defined as to be understood is another question. It commences with the declaration that a person shall not perform on a living animal any experiment calculated to give pain, except subject to the restrictions imposed by this Act.

Any person performing or taking part in performing any experiment calculated to give pain, in contravention of this Act, shall be guilty of an offence, and liable for a first offence to a penalty not exceeding 50*l.*, and for a second or subsequent offence, at the discretion of the court, to a penalty not exceeding 100*l.*, or to imprisonment for a period not exceeding three months. There are general restrictions as to the performance of painful experiments on animals. The experiments must be with a view to the advancement by new discovery of physiological knowledge or of knowledge which will be useful for saving or prolonging life, or alleviating suffering; the experiment must be performed by a person holding such license from one of Her Majesty's Principal Secretaries of State, and in the case of a conditional license, or of experiments for the purpose of instruction in a registered place, the animal must during the whole of the experiment be under the influence of some anæsthetic, of sufficient power to prevent its feeling pain; the animal, if the pain is likely to continue after the effect of the anæsthetic has ceased, or if any serious injury has been inflicted on the animal, is to be killed before recovery from the anæsthetic; the experiment shall not be performed as an illustration of lectures in medical schools, hospitals, colleges or elsewhere, and shall not be performed for the purpose of attaining manual skill. There are four provisos to the restrictions which are set forth. In the other sections there are special restrictions as to painful experiments on dogs, cats, etc. Any exhibition to the general public of experiments on living animals is strictly prohibited under heavy penalties, and any person 'publishing any notice of such intended exhibition by advertisement in a newspaper, placard, or otherwise, shall be liable to a penalty not exceeding 1*l.*' The Secretary of State may license any person whom he may think qualified to hold a licence to perform experiments, and may insert the place where they are to be performed, and may require reports to be made to him of such experiments. The Secretary of State 'shall cause all registered places to be from time to time visited by inspectors, for the purpose of securing a compliance with the provisions of this Act, and the Secretary of State may, with the assent of the Treasury as to number, appoint any special inspectors, or may from time to time assign the duties of such inspectors to such officers in the employment of the Government who may be willing to accept the same as he may think fit, either permanently or temporarily.' Any application for a licence and a certificate must be signed by one or more of the following persons:—The President of the Royal Society, the President of the Royal Society of Edinburgh, the President of the Royal Irish Academy, the Presidents of the Royal Colleges of Surgeons in London, Edinburgh, or Dublin, the President of the Royal Colleges of Physicians in London, Edinburgh, or Dublin, the President of the General Medical Council, the President of the Faculty of Physicians and Surgeons of Glasgow, and the President of the Royal Veterinary, etc., but in the case only of a experiment under anæsthetics with a view to the advancement, by new discovery, of veterinary science, and also by other persons mentioned. A certificate may be given for such time or for such series of experiments. A copy of a certificate to be forwarded by the applicant to the Secretary of State, but not available until one week after a copy has been forwarded. The Secretary of State may at any time disallow or suspend any certificate given under this (11th) section. A judge is empowered to grant a licence for an experiment when necessary in a criminal case. A justice may grant a warrant on grounds that experiments are made by unlicensed persons in places not registered under the Act, with penalties to be imposed. Offences may be prosecuted in a summary manner. A person accused may elect to be tried on an indictment, and not by summary jurisdiction. An appeal is given in England to the Sessions, and the manner of procedure in Scotland and Ireland pointed out. The Act is not to apply to invertebrate animals, and the medical profession is protected by the 21st section, which declares that 'a prosecution under this

Act against a licensed person shall not be instituted except with the assent in writing of the Secretary of State.'

UNIVERSITY OF LONDON. FIRST M.B. EXAMINATION.—The following candidates have passed the recent examination.—*Entire Examination: First Division.*—Charles Edward Baddeley, King's College; James Stanley Newton Boyd, University College; Charles Alfred Dagnall Clark, St. Bartholomew's Hospital; Mark Percell Mayo Collier, St. Thomas's Hospital; James Percy Alwyne Gabb, University College; George Aldridge George, University College; William Linton Heath, St. Bartholomew's Hospital; William Manley Lory, University College; Valentine Matthews, King's College; John Edward Neale, University College; Sidney Philip Phillips, University College; John Charles Saunders, Downing College Cambridge, and St. Bartholomew's Hospital; Charles Edward Sheppard, St. Thomas's Hospital; Kenneth Rawlings Smith, University College; Howard Douglas Stewart, King's College; John Caldwell Uthoff, Guy's Hospital; Robert Spencer Wainwright, Guy's Hospital; Neville Scott Whitney, University College; David James Williams, University College.
Second Division.—William Stratford Andrews, University College; Frederic Haycraft Berry, Guy's Hospital; Frederick William Slater Culhane, University College; Donald Frederick Dymott, University College; John Thomas Faulkner, Owens College; Walter Baugh Hadden, Liverpool School of Medicine; Charles Coleman Jewell, University College; Roger Hughes Jones, Liverpool School of Medicine; Henry Edward Juler, St. Mary's Hospital; Alfred Austin Lendon, University College; George Mackern, Guy's Hospital; Herbert Lynsey Manby, Guy's Hospital; Joseph Henry Marsh, St. Thomas's Hospital; William John Notley, B.A., University of Edinburgh; George Hannah Russell, Guy's Hospital; John Reynolds Salter, University College; Thomas Steele Sheldon, Guy's Hospital; William Samuel Tuke, University College.
Excluding Physiology: First Division.—John William Meek, Guy's Hospital.
Second Division.—Frederick Rowland Barker, St. Thomas's Hospital; James Richardson Andrew Clark, University College; Richard Hughes, Owens College; George Shaw, Westminster Hospital; John Hinks Vinrace, Queen's College, Birmingham; Dawson Williams, University College.
Physiology Only: First Division.—William Henry Blake, University College; Charles Henry Cuming, University College; Samuel Thomson Plumbe, St. Bartholomew's Hospital.
Second Division.—Alfred Edgar Drysdale, University College and Liverpool School of Medicine; William James Pickup, University College; James Ryley, University College; Herbert Urmsom Smith, St. Thomas's Hospital.
Examination for Honours.—Anatomy. First Class: John Charles Saunders (Exhibition and Gold Medal), Downing College, Cambridge, and St. Bartholomew's Hospital; James Stanley Newton Boyd (Gold Medal), University College. Second Class: Charles Edward Baddeley, King's College; Charles Edward Sheppard, St. Thomas's Hospital. Third Class: James Percy Alwyne Gabb, University College; William Lenton Heath, St. Bartholomew's Hospital.—Physiology, Histology, and Comparative Anatomy. First Class: William Samuel Tuke (Gold Medal), University College; John Charles Saunders (Gold Medal), Downing College, Cambridge, and St. Bartholomew's Hospital; John Edward Neale, University College. Second Class: John Caldwell Uthoff, Guy's Hospital. Third Class: George Mackern, Guy's Hospital; Neville Scott Whitney, University College.—Organic Chemistry, and Materia Medica and Pharmaceutical Chemistry. First Class: Kenneth Rawlings Smith (Exhibition and Gold Medal), University College; John Caldwell Uthoff (Gold Medal), Guy's Hospital; Neville Scott Whitney, University College. Second Class: Frederic Haycraft Berry, Guy's Hospital. Third Class: William Manley Lory, University College.—FIRST B.Sc., AND PRELIMINARY SCIENTIFIC (M.B.)

EXAMINATIONS.—Examinations for Honours.—Chemistry. First Class: Ernest Henry Cook, First B.Sc. (Exhibition), Royal College of Science, Dublin; Robert Maguire, Prel. Sci., Owens College. Second Class: William Henry Higgin, First B.Sc., Owen's College; Thomas Gough, First B.Sc., private study; James Hugh Paul, First B.Sc. and Prel. Sci., private study; Beaven Neave Rake, Prel. Sci., Guy's Hospital. Third Class: William Fream, First B.Sc. and Prel. Sci., Royal College of Science, Dublin; Henry Thomas Groom, Prel. Sci., St. Bartholomew's Hospital; Francis Bowe, Prel. Sci., St. Bartholomew's Hospital; James Norie, Prel. Sci., University College.—Zoology. First Class: David Alexander King, Prel. Sci., St. Bartholomew's Hospital. Second Class: Arthur George Dawson, Prel. Sci., Owens College; Charles Pardey Lukis, Prel. Sci., St. Bartholomew's Hospital; Mark Feetham Sayer, Prel. Sci., University College; William Evans Hoyle, First B.Sc. and Prel. Sci., Owen's College and Christ Church, Oxford; Wayland Charles Chaffey, Prel. Sci., St. Bartholomew's Hospital; Denis McDonnell, Prel. Sci., King's College. Third Class: Robert Henry Scanes Spicer, Prel. Sci., private study; Robert Maguire, Prel. Sci., Owen's College; Henry Thomas Groom, Prel. Sci., St. Bartholomew's Hospital.—Experimental Physics. First Class: Henry Forster Morley, B.A., First B.Sc. (Arnott Exhibition and Medal), University College. Second Class: Thomas Bolton, First B.Sc., University College. Third Class: Julian Stephens, First B.Sc. and Prel. Sci., University College and private study.—Botany. First Class: Joseph Tregelles Fox, Prel. Sci., London Hospital. Second Class: Anundrao Atmaram, First B.Sc. and Prel. Sci., University College; Robert Henry Scanes Spicer, Prel. Sci., private study; John Mitford Atkinson, Prel. Sci., London Hospital; Andrew William Dallmeyer, First B.Sc. and Prel. Sci., University College; Richard Sisley, Prel. Sci., St. George's Hospital. Third Class: Charles Pardey Lukis, Prel. Sci., St. Bartholomew's Hospital; Henry Thomas Groom, Prel. Sci., St. Bartholomew's Hospital.

UNIVERSITY OF EDINBURGH.—The following candidates received the degree of Doctor of Medicine, the degree of Bachelor of Medicine, and the degree of Master in Surgery, in the University of Edinburgh, on Tuesday, August 1.

Degree of Doctor of Medicine under the New Statutes. (** Those who have obtained Prizes for their Dissertations; * Deemed worthy of competing for the Dissertation Prizes; * Commended for their Dissertations.)—With the titles of their theses: Frederick William Barry, Scotland, M.B. and C.M., 1874. Diphtheria. * Johannes Aveticion Calantariants, Armenia, M.B., 1874. The Senses and the Undulatory Theory. James Angus Cameron, Scotland, M.B. and C.M., 1867. Obstetrical Notes and Cases. * Alfred Midgley Cash, England, M.B. and C.M., 1873. A Clinical Study and Analysis of a few Cases of Carcinoma. Thomas Dodson Chalmers, England, M.B., 1869. The Therapeutic Action of Change of Climate to Tropical Latitudes in some cases of Pulmonary Disease. * Holland John Cotton, England M.B. and C.M., 1874. Three Cases of Cerebral Lesion. John Sim Cowan, Scotland, M.B. and C.M., 1871. Dyspepsia. *** Daniel John Cunningham, Scotland, M.B. and C.M., with First-Class Honours, 1874. The Spinal Nervous System of the Cetacea, with an account of a hitherto undescribed variety of Dolphin. *** Edward Harriman Dickinson, England (M.A. Oxon.), M.B. and C.M., 1870. The Phenomenon of so called 'Direct' Paralysis. * Alfred Eddowes, England, M.B. and C.M., 1873. Erysipelas. John Alexander Gailey, Scotland, M.B., 1874. Typhoid Fever. ** Alexander James, Scotland, M.B. and C.M., 1872. The Physics and Physical Diagnosis of the Respiratory Organs. Johnstone Macfie, Scotland, M.B. and C.M., 1871. Notes of a few Cases of Chorea, with special reference to the relation of Chorea to Rheumatism. *** Charles Watson Macgillivray, Scotland, M.B. and C.M., 1873. Acute

Ulcerative Endocarditis, with Experimental and Microscopic Research on the subject. William Henry Murray, Scotland, M.B. and C.M., 1874. Diseases incidental to the Puerperal State. * Robert Fairman, Scotland, M.B. and C.M., 1872. On the Physiological Antagonism of Remedies. Robert Edward Phillips, England (M.A. Cantab.), M.B. and C.M., 1874. Preventive Medicine, its importance and some of its results. Henry Walter Plant, England, M.B. and C.M., 1874. Scarlatina. * Abraham Wallace, Scotland, M.B. and C.M., 1873. Sterility.

Degree of Doctor of Medicine under the Old Statutes.—Stewart Aaron Lithgow, Scotland. Contributions to Military Surgery from the Siege of Delhi.

Degrees of Bachelor of Medicine and Master in Surgery.—(a. Indicates that the Candidate passed the Examinations with First-Class Honours. b. Indicates that the Candidate passed the Examination with Second-Class Honours.) Robert Frederick Adams, Scotland; James Anderson, Scotland; James Baker, England; George Andreas Berry, Scotland; Joseph Senior Boothroyd, England; George Victor Louis Bouchet, Mauritius; Charles Boyce, Ireland. Daniel Catlin Burlingham, England; Robert Neill Campbell, Scotland; John Theodore Cash, England; Osborne Henry Channer, India; Thomas Frederick Chavasse, England; Robert Maxwell Clark, India; William Lennox Cleland, China; Charles Alfred Coleman, Nova Scotia; James Craig, Scotland; Alexander Lesslie Curro, Scotland; Michael Dewar, Scotland; Henry Dobson, England; (a) William John Dodds (B.Sc. Edin.), England; George Augustus Emerson, India; Montague Stokes Eyre, India; John Henry Suffield Finnis, Mauritius; George Alexander Gibson (B.Sc. Edin.), Scotland; (a) David Grant (M.A. Edin.), Scotland; James Dundas Grant (M.A. Edin.), Scotland; William Thomas Grant, Scotland; James Allan Gray (M.A. Edin.), Scotland; Henry Brougham Guppy, England; John Hassall, England; Henry Hay, Scotland; John Home Hay, Scotland; Robert William Irvine, (M.A. Edin.), Scotland; William Hadden Johnson, Australia; David Johnston Jones, England; Joseph Hay Keay (M.A. Edin.), Scotland; Charles Scott Kilner, England; Robert Kirk, Scotland; William Lamb, Scotland; George Lockwood Laycock, England; John Rudd Leeson, England; Simon Linton, Scotland; William Logie, Scotland; Alexander Lyall, Scotland; William Henry Maberly, England; Peter M'Bride, Hamburg; Thomas Ranken Macdonald, Scotland; Aymer Robert M'Dougall, Scotland; Hugh M'Laren, Scotland; David Menzies, Scotland; John Bell Miller, Scotland; Byers Moir, England; James Murray, Scotland; Thomas Goodall Nasmyth, Scotland; George Ogilvie (B.Sc. Edin.), Scotland; Leslie Ogilvie (B.Sc. Edin.), Scotland; John James Pringle, Scotland; James George Robertson, Africa; John Robertson (B.Sc., Edin.), Scotland; William James Rose (M.A. Aberd.), Scotland; Arthur Pickston Russell, England; William Russell, Isle of Man; Duncan Robert Stewart, Scotland; Edwin Pringle Thew, England; Abraham Garrod Thomas, Wales; Thomas Edgar Underhill, England; John James Underwood, England; Alexander Walker, Scotland; David Wylie Wallace, England; Bryan Charles Waller, England; Vincent Wanostrocht, England; Charles Henry Waterhouse (B.A. Lond.), England; Charles Scott Watson, Scotland; John Douglas Watt, Scotland; William Henry White, England; John Henderson Wright, Scotland; Alfred Harry Young, England.

Degree of Bachelor of Medicine.—Edward Leopold Baker, England; Arthur Richard Barnes, England; William Galletly, Scotland (received the degree April 20, 1876); William Henry Montgomery, America; Hans Jurgens Moolman, Cape of Good Hope; Robert Roxburgh, Scotland; (b) Andrew Smith, Scotland; Charles Edward Henderson Warren, England.

Degree of Master in Surgery.—Thomas Harker, England (received the degree April 20, 1876); John Bisset Smith, M.B. 1873 (M.A. Aberd.), Scotland. The Ettles prize was awarded to David Grant, M.A., M.B., C.M.

The London Medical Record.

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BOWDITCH ON THE FORCE OF CILIARY MOTION.

Dr. H. P. Bowditch, Professor of Physiology in Harvard Medical School, writes as follows in the *Boston Medical and Surgical Journal* for August 10.

Most observers who have studied the movements of cilia have directed their attention to the evidence of ciliary activity, afforded by the rapidity with which very light bodies are carried over the surface of the ciliated membrane. Thus Valentin (Wagner's 'Lexicon,' vol. i. p. 506) observed that the capsules of mucus on the gills of Anodonta were carried forward at the rate of four millimètres in one minute. Engelmann ('Flimmerbewegungen,' p. 70), in studying the various conditions which affect ciliary activity, made observations on the rapidity with which a small globule of sealing-wax, suspended by a light silk thread so as to merely touch the membrane, was moved forward over the ciliated surface. The rate varied in his observations from 7·8 to 24·5 millimètres in one minute. Calimburces (*American Naturalist*, vol. v. p. 611), also, in constructing his apparatus for measuring ciliary movement, made all the parts as light as possible, in order to reduce the work done by the cilia to a minimum.

The late Jeffries Wyman (Bernard, 'Les Tissus vivants,' p. 141) was the first to call attention to the fact that the force exerted by cilia is by no means inconsiderable. He describes his experiments on frogs as follows. 'The mucous membrane being carefully dissected from the roof of the mouth is pinned to a board. A piece of skin from near the throat of the frog, and from one third to half an inch square, is placed upon this membrane with the inner surface in contact with the cilia, it being kept in mind that these vibrate from before backwards towards the throat. On the skin may be placed a plate of lead of somewhat smaller size. This serves as a vehicle to which weights may be added at will to increase the load. . . . Pains should be taken to have the board on which the experiment is made perfectly horizontal, otherwise a sliding motion, especially when heavy weights are used, may come in to vitiate the experiment.' The rate of movement was determined either by direct observation of the lead 'vehicle' with its load, or by means of an index attached to the axle of the smaller of a pair of light cog-wheels, the 'vehicle' being connected with the apparatus by means of a thread coiled round a drum on the axle of the larger wheel. By experiments performed in this way it was found that a weight of 13 grammes was carried 15 millimètres in about one minute, the weight resting on a surface of 12 millimètres square, and that 48 grammes, resting on a surface 14 millimètres square, moved, though very

slowly, across the whole length of the membrane; but the exact time was not noted.'

It will be noticed that in these experiments the work done by the cilia consisted in overcoming the friction of the skin upon the membrane and of the parts of the index-apparatus on each other, and that the amount of this work, though increased by the addition of weights to the lead plate, was not, and could not well be, accurately determined. The weight being moved in a horizontal plane, there was no direct performance of work which could be measured by foot pounds or kilogrammètres. In view, however, of the evidently very considerable force of the ciliary movement, it seemed important to determine the maximum of work which could be performed in a given time by a given surface of ciliated membrane. The simplest way of accomplishing this object seemed to be to repeat Wyman's experiments, with the modification of giving to the board on which the membrane rested an inclination which would compel the cilia to move a weight resting upon them up an inclined plane. Then the product of the weight by the height through which it was lifted would give the value sought.

After several preliminary experiments, an apparatus was constructed, consisting of a piece of thin board about 11 centimètres square, with a narrow strip of wood about 7 millimètres in thickness fastened at the middle of one edge. A strip of glass 4·5 centimètres long, by 1 centimètre broad, with edges smoothed on a grindstone, was firmly cemented by one end to the middle of the strip of wood, and thus projected over the surface of the board, parallel to, and 7 millimètres from it. A frog with brain and spinal cord destroyed was then prepared as follows. A transverse incision, about 1 centimètre long, was made through the mucous membrane of the roof of the mouth as far forward as possible. The free end of the glass strip was inserted into this incision, and pushed back between the membrane and the bones of the palate. The lower jaw was then cut away, and the œsophagus laid open as far as the stomach. The cut edges of the œsophagus were kept extended by pins thrust through them into the board below. The frog thus lay upon the board with the body under the strip of glass, and the ciliated membrane from the anterior edge of the palate to the stomach smoothly stretched over it, and accessible to observation and experiment. A vehicle to be moved by the cilia was made by cementing a small oval piece of glass of 1·437 square centimètres area to a thin piece of wood of the same size. The glass surface was then covered with a piece of frog's skin stretched over it, with the inner surface outward, and held in place by a thread tied round it and lying in a groove cut in the end of the wood. This vehicle, when placed with the skin downward upon the ciliated membrane, was readily carried along toward the stomach. The work done by the cilia could be increased either by placing weights upon the vehicle, or by inclining the whole apparatus so that the vehicle should be carried up an inclined plane. The latter object was readily effected by means of a wedge pushed under the edge of the board opposite to the point where the glass strip was fastened. The wedge was so graduated that in every position it could be seen at a glance what proportion of the distance moved over by the vehicle was movement in a vertical direction. The movement of the vehicle was observed with a microscope of low power, furnished with an eye-piece micrometer. The

draw-tube of the instrument was so adjusted that thirty divisions of the eye-piece micrometer corresponded to 1 millimètre in the field of vision. A stop-watch was used to determine the time occupied by a chosen point on the vehicle in passing over these thirty micrometer divisions.

It will thus be seen that the data of observation in our problem were as follows :

a = grade per cent.; *i.e.*, the movement in a vertical direction expressed as a percentage of the distance moved, and determined by a simple observation of the position of the wedge.

b = weight in grammes of the vehicle and the load placed upon it.

c = time occupied by the vehicle in moving one millimètre.

d = area in $\frac{\text{centimètres}^2}{\text{centimètres}}$ of the surface of the vehicle

applied to the ciliated membrane.

The value to be determined by means of these observations was the amount of mechanical work, expressed in grammillimètres,* which was performed by one square centimètre of ciliated membrane in one minute. If we express this value by x we shall have the formula,—

$$x = \frac{a}{100} \times b \times \frac{60}{c} \times \frac{1}{d} = \frac{6ab}{10cd}$$

This formula expresses, of course, only the work done in raising the vehicle with its load. A certain amount of work is also performed in overcoming the friction of the vehicle on the membrane; but this amount is very difficult to determine, because the moving force is generated at the same point where the friction is applied. It is probably small in comparison with the work of raising the vehicle, and it was therefore disregarded.

A modification of the experiment consisted in placing the board in a perpendicular position, so that the vehicle, held in contact with the membrane by capillary attraction, was carried vertically upward. In this case $a = 100$, and the above formula becomes $x = \frac{60b}{cd}$. In order to obtain as great uniformity as

possible in these observations, it was, of course, important to avoid drying of the membrane. For this purpose a 0.5 per cent. solution of common salt, made very slightly alkaline with sodic hydrate, was applied from time to time to the membrane. The results were nevertheless by no means so uniform as could be desired. The following table may serve as an example of the experiments. In this case the grade was at first kept constant at 10 per cent., and weights of 5, 10, and 20 grammes placed successively upon a vehicle weighing 0.534 gramme. Afterward the board was placed in a vertical position, and observations were made on the rate at which the vehicle alone was carried upward.

It will be seen from the table, that by loading the vehicle the rapidity of its movement was diminished, but not in proportion to the increase of the weight. In other words, the greatest amount of work was obtained with the heaviest load. Thus the cilia, when compelled to carry a weight of 20.534 grammes up a grade of one in ten, performed in one minute for each square centimètre of surface an amount of work equal to 6.805 grammillimètres. This was the

maximum of work obtained in upward of one hundred observations made with various weights and grades; but it is not probable that it is the maximum of work which cilia are capable of performing. It is perfectly possible that under somewhat different conditions they may work to much better advantage.

A. Grade. Per cent.	B. Weight. Grammes	C. Time. Seconds	D. Area. Centimètres ²	$x = \frac{6ab}{10cd}$ Grammilli- mètres
10	10.534	10.8	1.437	4.074
10	10.534	7.4	1.437	5.940
10	20.534	15.	1.437	5.718
10	0.534	3.	1.437	9.743
10	5.534	5.6	1.437	4.127
10	5.534	5.	1.437	4.622
10	10.534	8.5	1.437	5.176
10	20.534	12.6	1.437	6.805
10	20.534	12.6	1.438	6.805
100	0.534	5.3	1.437	4.208
100	0.534	4.2	1.437	5.310
100	0.534	3.8	1.437	5.868
100	0.534	4.4	1.437	5.067
100	0.534	4.8	1.437	4.646
100	0.534	5.	1.437	4.460
100	0.534	5.	1.437	4.460

It will be noticed, for instance, in the above table, that, when carrying the unloaded vehicle vertically, they performed an amount of work nearly equal to the maximum obtained in carrying heavy weights up an inclined plane. It is not improbable that by altering the size, weight, or shape of the vehicle, conditions may be found under which the cilia may perform a greater amount of work than that here recorded. The investigation of this question will be the subject of a future series of experiments.

The statement that a ciliated membrane performs, per square centimètre per minute, 6.805 grammillimètres of work, gives a very imperfect idea of the force of the moving cilia, unless we obtain a conception of the bulk of the organs where this force is generated. It is generally believed, though not absolutely demonstrated, that the force which moves the cilia is generated in the protoplasm of the ciliated cells. These cells in the frog's mouth are spherical in form, with the cilia upon one side. The average of nine measurements gave a diameter of 0.016 millimètres, which agrees very well with Valentin's figures. If we imagine spherical cells of this size placed close together on the surface of the membrane, the volume of the cells on one square centimètre of surface will be 1.6 cubic millimètres, and their weight, if we suppose them to have the specific gravity of water, will be 0.0016 gramme. Thus we see that a mass of protoplasm weighing 0.0016 gramme performs in one minute an amount of work equal to lifting 6.805 grammes to the height of one millimètre. This is equal to lifting 0.0016 gramme to the height of 4253 millimètres. In other words, the ciliated cells perform in one minute an amount of work equal to lifting their own weight to the height of 4253 metres. It is interesting to compare this value with that obtained for the striated muscles of the heart. The work performed by the heart at each pulsation is equal to the weight of the blood expelled by the contraction multiplied by the height of a column of blood which measures the tension in the aorta and pulmonary arteries. From these data Schiff ('Physiologie de la Digestion,' vol. i. p. 24), has estimated that the heart does in one minute an amount of work

* This small unit of work was chosen merely for the sake of convenience in writing the results. It is, of course, one millionth of a kilogrammètre.

equal to lifting its own weight to the height of 150 mètres, a value more than thirty-five times as great as that above given for the ciliated epithelium.

WARREN ON VAGINAL LITHOTOMY.*

The following article is published by Dr. J. Collins Warren, surgeon to the Massachusetts General Hospital, in *The Boston Medical and Surgical Journal*, for July 20, 1876. We have made some slight abridgments.

In August last I was requested by Dr. Alexander Jackson, of Plymouth, to operate upon a case of calculus in the female bladder. The patient was sixty-seven years of age, and when I saw her for the first and only time, on the day of the operation, was in bed, appearing much emaciated and pale. She had been suffering greatly with symptoms of cystitis for the better part of a year, and, although previously healthy, had become a confirmed invalid. There were no symptoms of renal complications. She was the mother of several children. The patient, being etherised, was placed in the position for lithotomy in the male, and a lithotrite was introduced into the bladder for the purpose of determining the size of the stone. The examination showed that it was not a small one, and in view of the degree of inflammation of the bladder and her advanced age I decided to remove it by vaginal lithotomy. The operation was thus performed with the assistance of Drs. Stedman and Jackson. A large bulb-pointed probe was passed into the bladder, and its end made prominent beneath the mucous membrane of the anterior wall of the vagina, at a point just behind the neck of the bladder. An incision was made into the bladder at this point, the knife cutting against the end of the probe. A pair of probe-pointed scissors were introduced into the opening thus made, and the incision was enlarged backwards along the median line to the extent of one inch. The stone was extracted by a pair of polypus forceps. The bladder was then washed out with warm water, and the edges of the wound were brought in contact with six silver wire sutures. A female catheter was retained in the bladder, and the patient left in charge of Dr. Jackson, from whom I subsequently learned that she at first did well, and no urine passed through the wound. Two weeks after the operation there were symptoms of abdominal inflammation, and some leakage occurred through the wound. Two months later the condition of the patient had improved greatly, and under the application of caustic the slight fistula which still remained had closed, but had reopened at the end of forty-eight hours; Dr. Jackson had no doubt, however, that it would eventually close. Under the date of March 28, Dr. Jackson writes, 'Mrs. R. is about, feeling quite well, with the exception of a little cold recently.' The stone (examined by Dr. E. S. Wood) contained a nucleus, which was about the size of an almond-shell, consisting of oxalate of lime, its surface being coarsely crystalline. The cortical portion which was broken into several fragments during the examination, was phosphatic. The weight of the stone was 214 $\frac{3}{4}$ grs.

Vaginal lithotomy, or vesico-vaginal lithotomy, as it is sometimes called, is no novelty, although the operation has been much more frequently performed since the treatment of vesico-vaginal fistula has been

brought to its present degree of perfection. The employment of sutures to close the incision connecting the bladder with the vagina, has placed the operation on an altogether different footing. The first operation was performed by Rousset in the latter part of the sixteenth century, in a case of proctentia and cystocele, in the *cul-de-sac* of which was found a stone. Fabricius Hildanus removed a calculus through a vesico-vaginal fistula, caused by its presence in the bladder, in 1598. The operation was performed in the last century, and also in the early part of the present century, and was almost invariably followed by incontinence of urine resulting from fistula. Faure is, however, reported in 1808 as having avoided a fistula by cutting obliquely through the septum, and thus making a valvular opening into the bladder. The first case in which sutures were employed to close the incision occurred, so far as I can discover, in the practice of Dr. Marion Sims. A fistula remained, however, which was subsequently closed by Bozeman. This is probably the operation performed by Sims in 1850. Vallet, of Orleans, employed sutures in two cases in 1856. An interesting historical account of the various operations for stone in the female is given by Hybord (*Des Calculs de la Vessie chez la Femme et les petites Filles*. Paul Hybord. Paris, 1872). In 1853 Dr. William G. Wheeler (*American Journal of the Medical Sciences*, xxv. 361) of Chelsea (U.S.) removed a stone weighing two ounces and three-quarters, which had formed about a hair-pin three and one half inches in length through an incision in the septum. Sutures were not used, but the remaining fistula was closed many years afterwards by Dr. R. M. Hodges. Lithotomy was tried in this case without success. A case may be mentioned in this connection, occurring in the practice of M. Panas (*France Médicale*, February 26, 1876), who extracted a hair-pin from the bladder by forcing it through the vesico-vaginal septum. The puncture of the septum occurred accidentally during efforts at extraction through the urethra. The pin was drawn into the vagina, straightened, and removed. In four days the patient left the hospital, no trace of the puncture remaining. Dr. R. M. Hodges performed vesico-vaginal lithotomy sixteen years since, closing the wound by suture with complete success. Dr. Emmett has performed this operation more frequently than any other surgeon; and it is a curious fact that in nearly all of his cases the calculus had formed after an operation for the cure of vesico-vaginal fistula. In nearly every case, the cystitis was sufficiently severe to necessitate leaving the opening unclosed after removal of the stone. In some cases measures were taken to prevent closure of the wound, and when this was not done the wound healed invariably within two weeks. Dr. Emmet ('Chronic Cystitis in the Female,' *American Practitioner*, February, 1872) has treated a number of cases of chronic cystitis in the female by an incision through the vesico-vaginal septum. The wound was kept open by a hollow glass stud, not unlike a spool in shape. He thinks the operation, if resorted to before the disease has advanced so far as to involve the kidneys, is as free from risk as any minor surgery. He is satisfied that any one who has the dexterity properly to crush a stone by the female urethra can with much less difficulty close the fistulous opening after lithotomy.

This operation has rapidly increased in favour with many English surgeons. Dr. Aveling (*Obstetrical*

* Read before the Massachusetts Medical Society.

Transactions, 1864, v. 1) was one of the first to call attention to its advantages when followed by suture. He gives a table of thirty-four cases, and adds one operated upon by himself. Twelve of these were performed by English surgeons. In all of them there is but one death recorded. In twelve given by Hybord no death occurred. Aveling believes that, although lithotomy ought not to supplant the more simple process of dilatation and crushing, it should be employed when there is the least apprehension of incontinence. Mr. James R. Lane (*Lancet*, January 10, 1863) operated upon a case in which the stone was nearly two inches in length, dividing the septum to within a short distance of the attachment of the vagina to the cervix uteri. The patient recovered eventually without a fistula, although the edges of a small portion of the wound had to be pared and sewed together subsequently. He thinks there is no part of the vesical parietes which may be incised with so little risk, and that this operation is the safest and best which has yet been devised.

This procedure has not been confined to the adult. A number of cases have been reported where it was performed upon young children. Of these may be mentioned one by Mr. Thomas Smith (*Lancet*, December 17, 1870), the child being but five years of age. The incision was made and the sutures taken without rupturing the hymen. In a second case, in a patient ten years old, he made an incision through the fourchette before cutting through the septum; four sutures were taken in the vaginal wall, and three in the perinæum. The patient recovered without incontinence. Dr. S. H. Tewksbury ('Transactions of the Maine Medical Association,' 1871) removed a stone of the size of a pigeon's egg, through the septum, from the bladder of a girl seven years of age. The vagina was dilated gradually, and a small Sims's speculum was introduced, which brought the parts well into view. The sutures were removed on the fourteenth day, when the wound was found united. Dr. Tewksbury's paper contains much valuable information in regard to the history of the operation. He thinks that dilatation of the urethra is available in females who have borne children.

The operation has been performed by a number of American surgeons. Indeed, it seems to have been done more frequently in this country than in any other. Through the kindness of Dr. C. H. Mastin, of Mobile, Alabama, I have obtained a list of surgeons, with the number of cases operated on by them, thirty-five in number. Dr. Mastin speaks of six other cases, the names of the operators not being given, making in all forty-one cases.

I have recently obtained the notes of a case performed by Dr. H. O. Marcy, of Cambridge (U.S.), in April 1874. The patient, since her confinement, in February 1873, had suffered from cystitis. After an attempt at crushing, having first dilated the urethra, and failing through the size and hardness of the calculus, vaginal lithotomy was performed. The incision was made in the median line, commencing about one inch from the urethra, and was continued to include a small portion of the cervix uteri, to allow the extraction of the stone, which weighed over one ounce, and was rough and hard. It was chiefly phosphatic, and contained as a nucleus a few fibres of cotton. The wound was brought together with fine silver sutures, and united in its entire extent. A minute opening was left, however, at the point of entrance of one wire, which has not closed, although an attempt has since been made to close it.

It will be gathered from the testimony given above, that lithotomy is not a difficult operation to perform on the female. This fact appears to have struck forcibly all operators at their first effort, and none more so than myself. The patient being placed in the position for lithotomy, when the labia were separated the anterior wall of the vagina was seen hanging like a curtain at the mouth of the vagina. So superficial was this part, that it could be incised and sewed with nearly as much facility as the perinæum. The operation appears to be attended with little or no danger, hardly a single death being reported; on the contrary, in cases where the attending inflammation is severe, we find that it not only removes the cause but exerts a curative influence upon the inflammation itself, provided we simply avoid using the suture. The only real danger is from a failure of union of the wound; and this, with our present knowledge of the treatment of vesico-vaginal fistula, has been reduced to a minimum. Incontinence resulting from this cause is far more easily remedied than that which follows from over-distention and paralysis of the urethra.

A very old method of removing calculi from the female bladder, and one which has been growing greatly in favour of late, is extraction through the dilated urethra. Franco ('*Traité des Hernies*,' p. 140) proposed this operation in 1561. Collot combined dilatation with crushing in 1669. This was a favourite method with Sir Astley Cooper, who performed it three times without incontinence resulting. Dr. Yelloly (*Medico-Chirurgical Transactions*, vol. vi. 1815) mentions a number of cases where stones of extraordinary size have passed the urethra. In a case which occurred in his own practice the stone weighed over three ounces. In another case the patient, having suffered greatly, and after having experienced 'an uncommon weight and forcing' on one occasion, brought away, 'with a noise which very much surprised the whole company,' a stone seven and a-half inches in circumference. In all the cases given by him there was permanent incontinence subsequently. This danger of incontinence appears to have been recognised at an early period. Tolet ('*Traité de la Lithotomie*,' Paris, 1708) found that, if dilatation were excessive, the fibres of the urethra could not contract, and incontinence followed. Brodie ('*The Works of the late Sir Benjamin Brodie*,' ii. 649) says, 'I suspect that there is no method of removing it entire from the female bladder, without incontinence of urine to a greater or less extent being a consequence of the operation.' Vaginal lithotomy with suture was of course not then known. In three out of ten cases mentioned by Hybord, there was incontinence subsequently. Mr. Bryant (*Medico-Chirurgical Transactions*, vol. xlvii.) reports two cases of calculus removed by rapid dilatation, which was effected by Weiss's dilator. In his first case the shortest diameter of the calculus was one inch, and the age of the patient fifty-two years. In the second case, although the stone was caught in one of its shortest diameters, it measured with the forceps exactly two inches. The patient was thirty-five years old. In both cases was control gained over the bladder for several hours. Mr. Bryant has collected twenty-eight cases, in thirteen of which slow dilatation was employed, and in fifteen rapid dilatation. Among the former there were four cases of incontinence; in three of these, however, the stone was very large; among the latter there were none. He much prefers rapid dilatation, and states that 'in

children calculi one inch in diameter, and in adults two inches, may be safely removed by these means.' Mr. Bryant extracted a lady's stiletto from the bladder, guiding it by the finger introduced through the urethra. No incontinence followed.

Spencer Wells cautions against dilatation. A large stone, he says, may be removed and no incontinence follow, but incontinence might result from the removal of a very small calculus. (In one of Bryant's cases of incontinence, the stone was not large.) Incisions into the urethra he thinks more dangerous still, and mentions cases in the practice of a surgeon of large experience where it had been done in two adults and seven children, but 'they were all dribblers.' He prefers lithotomy. Lane is decidedly of the opinion that dilatation of the urethra should be employed only in the removal of stones of small size, the risk of incontinence being great, and the result incurable. The facility of dilatation renders it highly tempting to the surgeon, while the safety and bloodlessness commend it strongly to the patient. The consequence is, that it has caused many an unfortunate woman to pass the rest of her days in a loathsome and miserable condition. No stone, he thinks, larger than an acorn should be removed in this way from the adult, and none larger than a horse-bean from a child. He condemns strongly all incisions into the urethra.

When a stone is suspected, Christopher Heath (*Medical Times and Gazette*, April 11, 1874) does not hesitate to explore the bladder with the forefinger, previously introducing the little finger or dilating with the dressing forceps. He finds in all cases that have undergone this manipulation a split in the mucous membrane under the pubes, and some incontinence for twenty-four hours. After this, the patient ordinarily recovers complete control over the bladder. In one case a stone three-fourths of an inch in diameter was removed from a child, aged eleven years, through the urethra, and subsequently a fragment of a second stone, weighing 408 grains. Incontinence in this case was permanent. For such a case, he would recommend vaginal lithotomy. He cautions against the mistake of making the incision too small, the edges of the wound being bruised by a stone too large to pass through easily. He thinks there is no danger of wounding the peritoneum, even if the incision be carried up to the os uteri. In taking sutures both the vaginal and vesical walls should be included. He has operated three times; in two cases the wound healed by first intention, in the third there was a slight fistula. In one of the successful cases the calculus weighed three and one-half ounces. The ages of the patients were forty-nine, forty, and fifty years respectively (*Transactions of the Pathological Society*, vol. xxvi.).

During the past year, medical writers have had a great deal to say about the treatment of cystitis by dilatation of the urethra. Dr. T. W. Howe (*New York Medical Record*, August 14, 1875) reported a case of cystitis cured in this way. Mr. Pridgin Teale has written on the subject in the *Lancet* for November 27, 1875. He and several of his colleagues have employed this treatment for some time past with satisfactory results. This method consists in slowly dilating the urethra by a Weiss's dilator, until the fingers can be introduced into the bladder. It is noticeable that in three instances death occurred within a short time after the operation; there was in these cases, however, disease of the kidneys. Two cases suffered from incontinence afterward, and Mr.

Teale makes the significant remark, 'It does not, however, appear that the liability to permanent incontinence depended upon the degree to which the dilatation was carried.' Hewetson (*Lancet*, December 4, 1875) and Heath (*Lancet*, December 11, 1875) have both written upon the subject. Dr. George Jewett (*The Journal*, January 27, 1876) removed a crochet-needle by introducing the index finger into the bladder through the urethra. He noticed a slight rupture at the meatus during his manipulations, but there was no incontinence. The most accurate measurements which have been taken to determine precisely how much the urethra may be dilated without running the risk of incontinence are those made by Professor Simon, of Heidelberg, and published in Volkmann's *Sammlung Klinischer Vorträge* (translated in the *New York Medical Journal*, October, 1875) in July last. He recommends smooth, hard India-rubber plugs of different sizes, by which, when combined with incisions of the orifice of the canal, dilatation may be accomplished without rough handling of the urethra. This limit is two centimètres or 0.8 inch in width, and 6.3 centimètres or 2.4 inches in circumference. Dilatation to this size permits the index fingers of most surgeons to be passed with ease into the bladder. Simon's finger was small enough to enable him to pass at the same time a very slender instrument. A pair of polypus-forceps, such as Mr. Heath uses, would, if introduced at the same time with the finger, as he recommends, stretch beyond this limit. A stone must obviously be a small one to be removed by an instrument delicate enough to pass so narrow a space. Hyjord puts the limit of dilatation as high as three or four centimètres. Dr. W. W. Lawrence reports in the *Louisville Medical News* a case of a stone in a girl five years of age. The urethra was dilated with the fingers, and crushing was combined with extraction. It is not stated whether there was any subsequent incontinence. Dr. D. W. Yandell reports in the same journal a case of bilateral urethral lithotomy in a girl eleven years old. The stone was crushed before removal, and weighed two ounces. There was perfect recovery. In a second case, a girl four years of age, the urethra was divided on a director a short distance behind the meatus, for the extraction of a uric acid calculus the size of a filbert. Incontinence is not mentioned. Dr. Hergott, in an article in the *Annales de Gynécologie*, January 1876, gives three cases in which dilatation was practised for removal of growths from the bladder. An instrument was introduced with the finger, and the operation was continued in each case upwards of an hour. The limit given by Simon was not exceeded, and no incontinence followed. In one case, the author contemplates removing a remaining portion of the growth through an incision in the vesico-vaginal septum. He mentions several cases where coitus was performed through the urethra. Mention of this fact has also been made by other authors. Incontinence of urine was not present in these cases. Notwithstanding that many successful cases of dilatation with or without crushing have been reported, a high authority in America expresses himself strongly against this operation. Dr. Emmett, in his work on vesico-vaginal fistula, says, 'Comparatively, I do not regard the removal of stone in the female by the urethra as either a safe or a justifiable operation, in consequence of the great risk of incontinence of urine which frequently remains permanent. I have seen at least

seven cases in support of this assertion for which no relief could be afforded, and in which I am satisfied that the accident had not resulted from want of skill on the part of the operator.'

An interesting clinical lecture by Dr. Hunter McGuire (*West Virginia Medical Student*, May, 1876), gives the history of a case of vaginal lithotomy in a negress forty years of age. The stone was two and a half inches in diameter. Ten wire sutures were taken and removed on the eighth day, a catheter being retained a few days longer for safe union. Dr. McGuire states that many cases of so-called successful operations by dilatation and extraction have, to his personal knowledge, been followed by incontinence, the term 'successful' referring to the extraction of the stone. He says, 'We all know how easily a surgeon can introduce his finger into the female bladder when the woman is under the influence of chloroform,' 'but it certainly is not always safe to do this.' In a case at present under his care, a lady twenty-four years of age had been suffering from chronic cystitis, which resisted the usual remedies, and the physician had introduced his finger through the urethra to explore the bladder. Complete incontinence of urine followed. On examination, he found the meatus contracted to probably its original size, but the vesical end of the urethra and mouth of the bladder loose and relaxed, with all sphincter power destroyed. He proposes to make a vesico-urethra-vaginal fistula by removing an elliptical-shaped piece of the septum, and to close it by silver wire sutures in the ordinary manner. He does not believe it is ever necessary to introduce the finger into the female bladder for the sake of diagnosis. A stone over half an inch in diameter should not be removed *per urethram*. He condemns urethral lithotomy as leading almost invariably to incontinence. Lithotripsy, he thinks, is more difficult than in the male. The absence of the prostate gland and of the smooth fixed trigone which we find in the male bladder, the slight prolapse of the posterior wall found in almost all women who have borne children, the sometimes sacculated or perhaps displaced bladder, are some of the more important explanations of this difficulty. Byford is opposed to lithotripsy for similar reasons. Dr. Savory, of Lowell, informs me that he has had a case of incurable incontinence following dilatation for the removal of a stone of small size.

Sponge-tents have been employed to dilate the urethra for the purpose of removing calculi. They may be useful when the patient dreads anaesthesia, or when the stone is so small as to be voided spontaneously by the bladder on removal of the sponge. This occurred in a case in the practice of Dr. George H. Bixby, of Boston, where eleven small calculi came away upon the removal of a sea tangle tent. Dr. H. R. Storer has lately removed a calculus in this way without incontinence subsequently.

Dr. Buchanan of Glasgow, (*Medical Times and Gazette*, May 3, 1862), has performed the operation known as lateral lithotomy on a girl six years old. The operation resembles closely that performed on the male. A rectangular staff being introduced and held under the arch of the pubis, an incision is made into the left nymphæ, care being taken to avoid opening the vagina on the one hand and cutting too near the tuber ischii on the other. The left forefinger, introduced into the wound, feels with its nail the staff, and the knife guided along the nail is passed through the neck into the bladder. In his case there

was some difficulty in retaining the urine at the last account. Dr. Morton operated in this way on six cases, with what is stated to be a favourable result. Mr. Lane believes it to be an excellent operation, and admirably adapted for children. Dr. David Foulis (*British Medical Journal*, no. 786, page 115), made a dissection of the bladder of a woman on whom this operation had been performed twenty years before, and who died of renal dropsy. A conical opening was found in the left labium minus, from which ran a canal opening into the urethra and also into the vagina. The patient had been able to retain her urine, however.

In examining the records of the Massachusetts General Hospital, I find from 1821 to 1868 seventy-nine cases of stone reported, of which nine were in females. From 1821 to 1871, a period of fifty years, there were but ten cases of stone in the female. Of these calculi two were extracted through vesico-vaginal fistulae, one being removed entire, the other being crushed previous to extraction. Five were treated by lithotripsy, and in three cases the stone was extracted through the dilated urethra. Of the latter, one was a stone weighing two hundred and eighty grains; the urethra being dilated, it was seized by a pair of forceps and attempts were made to crush it, but without success. It was finally extracted through the urethra. Death occurred two days later, and at the necropsy the urethra was found considerably dilated, and in that portion below and a little on the right of the arch of the pubis was an irregular laceration more than one inch in length, extending into the bladder. It had the appearance of being due to sloughing of the part. The ureters were dilated and the kidneys diseased. In the two cases the urethra was found considerably dilated before the operation. In one a stone three-fourths of an inch in diameter was extracted and no incontinence followed. In one case three calculi were extracted, one being the size of a large peach-stone. There was a small fistula in this case, which was subsequently operated upon. The records of many patients operated upon during this period are not to be obtained, they having been treated as out-patients. Dr. C. B. Porter has recently removed a calculus from the female bladder through the dilated urethra. The calculus was partially crushed previous to extraction. Dilatation was not carried beyond Simon's limit. There was no incontinence.

There are several methods of treating stone in the female which have not been discussed in this paper. Lithotripsy, for instance, has been scarcely alluded to. My object has been to contrast the operation of vaginal lithotomy with one which has been employed in a class of cases to which that operation is mainly suited, and to discuss the comparative merits of two methods of operating which are now coming into fashion.

WATSON ON A SUPPOSED CASE OF CANINE RABIES TREATED WITH STRYCHNIA AND WOORARA; RECOVERY.

Dr. B. A. Watson, Surgeon to the Jersey City Charity, relates the following case in the *American Journal of the Medical Sciences* for July, 1876. On February 6, 1876, between ten and eleven A.M., Dr. Watson was summoned in great haste to see Mr. McC., of Jersey city, aged about forty-five, a strong, able-bodied man of temperate and industrious habits, who had previously enjoyed uniformly good

health. He found him in his sleeping apartment, suffering from a severe chill, which was accompanied by chattering of the teeth, violent retching, and the occasional vomiting of a little dark grumous fluid. There were suffusion of both eyes, equal dilatation of the pupils, marked congestion of the conjunctiva of the right eye, but slighter of the left, turgescence of the vessels of the face, giving the countenance a livid appearance. Respiration was sighing, pulse frequent and irregular, and the tongue furred, greyish white. He was highly nervous, apprehensive, and unwilling to be left alone. He said 'there is a sensation of tightness or squeezing' over the præcordial region. In answer to a question, 'How do you feel?' he replied, in a nervous, jerking voice, 'I am all right—nothing the matter with me.' He then called for a glass of water, which he took and tremblingly drank, evidently to show that he did not have hydrophobia.

Dr. Watson directed him immediately to be put into bed, well covered with blankets, mustard to be applied to the epigastrium, bottles of hot water to be placed around him, and the temperature of the room to be raised as soon as possible to 80° Fahr.

Dr. Watson learned from the family the following history. On or about November 25 last, Mr. McC. was presented with a young Newfoundland dog, which appeared at the time to be in a healthy condition; it was playful and good natured, ate and slept well; but within a month exhibited signs of illness, becoming restless, frequently starting up from apparent sleep, growling, barking, and snapping at imaginary objects. Soon after these symptoms were observed, the dog bit the servant girl, both of Mr. McC.'s children, and a young nephew. Mrs. McC., being now terribly alarmed, informed her husband that the dog was sick, and insisted that it should be sent away. The husband proceeded to examine the dog; and, while thus engaged, was bitten through the index finger of the right hand near the root of the nail. The examination being satisfactory, the dog was drowned. The wound readily healed. These events occurred about December 20 last. The servant girl (previously mentioned as the first one bitten by the dog) died February 1, 1876, of unmistakable rabies.

Mr. McC. had been complaining for a week or ten days prior to this visit. He had been low-spirited, melancholy, nervous, irritable; had taken little food, complained of shooting pains through various regions of the body, and other abnormal sensations which he was unable to describe fully. On February 5, he went to the Jersey City Opera House at the solicitation of his brother, who thought the entertainment given there might possibly dispel the melancholy, and relieve the nervous agitation with which he was suffering. Having remained there a short time, he informed his brother that he was too ill to stay any longer, and then went home. The patient attributed all these symptoms to a cold. On February 6, he arose at the usual time, took more breakfast than at any time during the previous week, but, feeling unwell, he lay down and soon fell asleep. After sleeping two or three hours he suddenly awoke, and calling his family, a messenger was immediately sent for Dr. Watson. Having obtained the foregoing history, Dr. Watson ordered one-twelfth of a grain of strychnia every three hours, and directly sent a messenger for Professor Flint, of New York, with whom a consultation was held at 4 P.M. At this time the pulse was 76;

respirations 11; inspirations sighing. He did not complain of any 'sensation of tightness or squeezing' over the præcordial region, or of pain in the hand or arm, which had been present three hours before. It was determined to continue the treatment with strychnia for the present. At 7 P.M. one ounce of Rochelle salt was ordered.

February 7, 9 A.M., pulse 78; respirations 12; inspirations slightly less sighing than yesterday. Bowels moved twice during the night. Face less livid. Less congestion of the conjunctivæ. He had some sleep during the night; he complained of being thirsty. He had taken considerable food at Dr. Watson's solicitation. His condition remained about the same throughout the day.

February 8, 9 A.M., pulse 84; respirations 11; inspirations still sighing. He had little sleep during the night, but had taken an abundance of nourishment. A sensation of tightness and squeezing over the præcordial region returned during the night, but was not constant. Poultices were applied over the thorax. He was now perspiring freely. At 12, noon, he was suffering with ærophobia; a slight current of air caused shuddering, the countenance at the same time expressing intense anxiety, mingled with dread. He had just suffered severely with a paroxysm caused by a current of air from the door which opened from his room. There was much muscular twitching, which extended over the whole body. The patient's thirst was very much increased, and he was more apprehensive. He was no longer satisfied with the presence of half a dozen friends in the room, but wished the room crowded. He was unusually talkative. At 5 P.M. a dose of Rochelle salt was ordered. At 10 P.M. ærophobia was slightly increased.

February 9, 9 A.M., the bowels were moved freely during the night. A paroxysm came on at 1 A.M., and lasted until nearly 2 A.M. This paroxysm was apparently excited by finding himself in the room with no other attendant than his wife. He seemed greatly frightened when he awoke, looked wildly around the room, and called in frenzied tones for his brother and other attendants who had been with him until near midnight. The strychnia was omitted from midnight until 11 o'clock this morning, without the knowledge of the attending physicians. The patient imagined the medicine was injuring him. At 2 P.M. he took one-twelfth of a grain of strychnia, and at 5 P.M. the same quantity. He now asked Dr. Watson if he would allow him to drink water; and an attendant asked him if he would have some. He refused, although he was complaining of great thirst. One of the principal attendants informed Dr. Watson that the patient had not taken a drop of cold water during the preceding twenty-four hours, and could not be persuaded to make the attempt, but that he had taken warm drinks freely. 10 P.M. no change.

February 10, 9 A.M., pulse 80; respirations 17. He passed a very restless night, with very little sleep; he did not take nourishment well. He had one paroxysm during the morning. 1 P.M., pulse 100; respirations 15. He had considerable muscular twitching; nervous, and more apprehensive. At 5 P.M. he had another paroxysm. Pulse 120, and all other symptoms proportionally intensified. At 7 P.M. he had just recovered from another paroxysm; gaseous eructations were now very distressing. He had just vomited. At 10 P.M. pulse more rapid; he was more nervous and apprehen-

sive; there were more muscular twitchings, and he was greatly distressed with gaseous eructations. At 11.30 P.M., he had a paroxysm, which was described by Dr. McLoughlin as follows. 'The paroxysm consisted of clonic spasms of the respiratory muscles, each lasting one or two minutes, followed in quick succession by others, and each succeeding one increasing in duration and severity, without any complete intermissions. At the end of an hour the spasms had become so severe and the dyspnoea so great, that he could not speak above a low whisper, and even this whispering was of short duration; from the commencement of the paroxysm the voice had become gradually lower and lower, so that finally he made his wishes known to his attendants by beckonings. During and after the paroxysm he was extremely sensitive to changes of temperature, the slightest current of air causing the paroxysm to recur. At his desire the temperature of the room was kept at 82° Fahr. During the paroxysm he was constantly calling and beckoning for poultices, which were applied at the highest temperature consistent with the feelings of the patient, as only a slight increase of temperature was needed to produce a blister. He afterwards told us that he thought the hot poultices afforded him some slight relief. The face and manners of the patient during the paroxysm indicated the highest degree of anxiety and alarm, but he was apparently conscious, and at that moment seemed to keenly appreciate the peril of his situation. When able to speak, he called on me in anxious tones for help; begged me to do something to relieve him. At 1 o'clock the paroxysm began to remit, and had wholly ceased at half past one. He was frequently expectorating tenacious saliva. Respirations were gasping and irregular. The severity of this paroxysm satisfied me at the time that he could not possibly survive four more of equal severity.'

The patient had been unusually talkative during his entire illness, but, as soon as he had recovered sufficiently from the exhaustion produced by the last paroxysms he talked incessantly, appeared unable to stop, and would not allow others to speak or in any way to interrupt him. He had made up his mind to die, and seemed resigned to his fate; but when Dr. Watson entered the room in company with Dr. McLoughlin for the purpose of injecting woorara, he requested them to wait, and then proceeded to say adieu to his numerous friends assembled around his bed, some of whom he admonished of future danger, and at the same time urged them to a higher and better life.

February 11. 2 A.M. One-sixteenth of a grain of woorara which he injected subcutaneously. During the previous twenty-four hours he had slept very little; twenty minutes after the injection he fell asleep, the sleep being disturbed and restless, occasionally starting up and then falling asleep again. At 5 A.M. being in an adjacent room, Dr. Watson heard the patient wrangling with his friends, having already thrown off the poultices and bedding, in opposition to their remonstrances and even resistance. When he entered the room he immediately recognised him; asked where he was and what was the matter with him. Dr. Watson informed him that he was at home and that he was very ill. He replied 'This is very strange! very strange! I can't understand it,' and then asked 'how long have I been sick?' and immediately following the question with the declaration 'I am no longer sick; I have only a sore throat.' He was now con-

stantly putting his hand to his throat, hawking and making a great effort to clear the same, but apparently with little success. He was persuaded to lie down in bed, and to permit the bedding to be again placed over him; and within a few minutes he was able to recall the past, and soon became perfectly rational. This delirium was of short duration, did not continue more than half an hour, and was the only attack of the kind from the commencement to the termination of the disease, and had been preceded immediately by retching and vomiting. Dr. Watson now injected one-ninth of a grain of woorara, after which he slept better and exhibited less nervousness. At 8 A.M. he injected one-sixth of a grain of woorara, which was followed by a quiet sleep. At 10 A.M. the patient was quiet and rational; pulse 96; respirations 17; no sighing. He declared that he was feeling perfectly well; was wholly indifferent to currents of air, in fact, all unfavourable symptoms had disappeared. Thinking it better to continue the use of the woorara, Dr. Watson requested Dr. McLoughlin to inject one-sixth of a grain at 11 o'clock. The patient refused the injection, but took a bottle of citrate of magnesia without the advice of his medical attendants. He had no return of the symptoms of the disease.

Dr. Watson reviews so much of the daily reports as may seem necessary to establish the true nature of the disease. The chill from which the patient was suffering when Dr. Watson first saw him, had disappeared previous to his second visit, and did not again appear. The retching and vomiting present on the first day returned on the third and fourth days, and became so troublesome on the fifth day that the patient was unable to take any appreciable quantity of food, and less than half the quantity of brandy which he had taken during either of the two preceding days.

He also complained very much of the strychnia; said 'it nauseated him,' and owing to this condition only a small quantity was taken, and a still smaller quantity remained in his stomach, probably less than one-fourth of a grain during the entire day was retained, as he vomited occasionally immediately after taking this medicine. There was a gradual increase in the severity of these symptoms during the whole disease, and no cessation until after the woorara was administered. Congestion of the conjunctivæ and the turgescence of the vessels of the face steadily diminished, and had entirely disappeared on the morning of the fourth day. The contractions of the respiratory muscles were paroxysmal in character, confined entirely to this group, at least affecting only the larynx, trachea, and lungs. Dilatation of the pupils existed three days. Nervous excitability, apprehensiveness, dread of being left alone, and sighing respiration, were present during the entire disease; although varying in intensity, apparently much increased by the clonic spasms of the muscles; but these all disappeared with the use of the woorara. The respirations varied greatly; at times being remarkably slow, but gradually increasing in rapidity towards the termination of the disease. The sharp lancinating pain in the left hand and arm was of short duration, probably lasting two or three hours. The pulse was variable; always more rapid during and immediately after the spasm, and more irregular and feeble.

The aerophobia made its appearance on the third day of the illness, and increased uniformly until the injection of woorara put an end to all further trouble.

The patient was not apparently affected by bright light, the light of any shining object, or by bathing the hands and face in water. The *aërophobia* alone indicated the excessive *hyperæsthesia*.

He complained slightly of thirst on the second day, which gradually increased until the morning of the sixth day, and on the fifth day gave him much suffering. Soon after the beginning of the thirst he endured very much pain from a sensation of fullness, and great distress in the *præcordial* region, which were accompanied with gaseous eructations. The last-mentioned symptoms followed the same course as the third—especially the gaseous eructations, which became extremely troublesome on the fifth day.

Early in the disease he began to perspire freely; day after day it increased, until finally the bed and bedding were thoroughly saturated with the perspiration, thus giving the patient the benefit of a continuous hot bath; but here again the cessation came when the *woorara* was injected.

The only aversion to fluids was manifested by the patient refusing to take cold water on the third day of his illness, and persistently thereafter until his recovery was established; although constantly complaining of thirst during this period, he only drank warm fluids in considerable quantities.

The patient endeavoured to convince himself and friends during his illness that he was not suffering with rabies; especially was this the case when free from pain and distress, and a few hours free from a paroxysm, but on the fifth day, the paroxysms being frequent, the suffering severe and continuous, his countenance became greatly dejected, and he now apparently abandoned the only hope that had previously cheered him.

He had previously imagined that all his illness was caused by the medicines, and consequently blamed his medical attendants; but during this day his confidence in them seemed to be fully restored, and he begged them frequently for relief, and desired them constantly at his bedside. The most singular part of his conduct is, that so soon as he found himself completely relieved, and again placed on the highway to health, his old fancy returned, and he now pretends to believe that the only cause of his suffering was due entirely to the medicine.

In further commenting on this case, Dr. Watson makes the following remarks. The important question to determine in connection with this case now is entirely one of diagnosis. Do the facts and symptoms warrant the conclusion that this patient suffered with genuine rabies *canina*? This question raises another, which has a prior claim on us at this time. How is the diagnosis of rabies made? Is there any pathognomonic symptom of this disease? The last question must certainly be answered in the negative, although the vulgar belief is that the inability to drink water, or at least great aversion to it, constitutes the principal phenomenon, and even among physicians it is not unusual to speak of this symptom as the characteristic one of the disease.

Inability to drink water is, however, found to exist in many other diseases, particularly hysteria, spurious hydrophobia, and many morbid conditions of the throat (*vide* Elliotson, S. Cooper, Poland, Romberg, etc.). On the other hand, there are a few well-authenticated cases, terminating fatally without the presence of this symptom. The case of Robert Hodson, who was bitten by a rabid dog, which died soon after inflicting the wound, is reported by

Samuel Cock, who says: 'He had no dread of liquids, nor did he ever refuse drinking what was offered to him, when he was sensible enough to understand what was meant by the offer. . . . He was now put into a tub of warm water, up to the chin, which did not the least discompose him, and when he got to bed again, he said he had no pain anywhere.'

Mr. Holmes Coote says, that 'in the course of thirty-five years' observation at St. Bartholomew's, . . . he 'saw only two cases of hydrophobia; and one of these so far belied the vulgar pathology as to the patient's repugnance to water, that the sucking of ice gave him the greatest relief.'

Another symptom of rabies—the clonic spasm—demands attention. The authorities who have written on the subject of rabies, do not fully agree in regard to the muscles principally affected by the spasms in this disease; probably for the reason that it seldom happens that the same group are equally affected in different cases, although there are very few, if any, cases in which the muscles of respiration are not largely involved.

As regards the diagnosis and treatment, Dr. Watson says: 'I have carefully examined the symptoms of this case, but have failed to produce anything like a satisfactory image of tetanus, hysteria, pseudo-hydrophobia or phrenitis. Had the case terminated fatally, probably no physician could have been found who would have questioned the correctness of the diagnosis rabies *canina*; but, notwithstanding the fact that the patient is now alive, I am still firmly convinced that the diagnosis was correct.

'In reviewing the development of this case, which has terminated thus favourably, so unexpectedly to myself and the medical gentlemen who have seen the case with me, I shall detail the management from the beginning to the end of the disease, and also mention some of the reasons for the selection of the remedies used. The strychnia was intended to be used regularly in the prescribed doses throughout the entire day, except while the patient was sleeping. I am, however, satisfied that it was not at all times taken with perfect regularity. The entire quantity of this drug used during the five days' illness of the patient was about two and one-fourth grains. It was our intention, when we commenced the use of the strychnia, to continue it in gradually increasing doses until its specific action was produced; but the patient did not take the medicine with that degree of method which insures confidence, and enables a physician to push the use of such powerful remedies until the desired effect has been attained. I am now satisfied that the plan of administration adopted by Dr. Fell in the treatment of tetanus with strychnia is highly advantageous, and should be followed in all cases of hydrophobia where this drug is used.

'The selection of this remedy for this case was based on the following reasons. 1. Rabies and tetanus belong to the same class of diseases, and the medicines used advantageously in the latter ought, therefore, to be beneficial in the former. 2. If we can rely on the published reports of cases of tetanus cured with it, then we are fully assured that no remedy has ever been previously used with anything like the same success. Finally, the treatment of rabies with the remedies heretofore used has not been sufficiently successful to justify a very strict adherence to any particular drug or method.

'The injections of *woorara* were given by myself, and I am, therefore, able to speak positively in the

daily report. The specimen was procured through the kind assistance of Professor Austin Flint, and was in a solid state. I requested Mr. Phillips, of this city, to prepare it for use, and have received from him the following note. "The solution of woorara for hypodermic injection was prepared as follows. One grain of woorara was first reduced to a fine powder, and to it was added with constant stirring one fluid drachm of distilled water. Alcohol of 95 per cent. was now added, drop by drop, till a nearly perfect solution was obtained. Sufficient diluted alcohol of the U. S. P. was then added to make the solution measure two fluid drachms. Prepared in this way, twelve minims of the solution should represent one-tenth of a grain of the drug. The slight turbidity of the preparation was probably owing to extraneous matter which existed as an impurity."

"The woorara was finally used because of its well-known physiological action, and also for the reason that the strychnia, which at first seemed to be highly beneficial to the patient—and I am fully satisfied that it did delay the progress which the disease would otherwise have made—could no longer be given on account of the vomiting."

"The conviction that I have just expressed in regard to the action of the strychnia is based on the fact that the patient after each paroxysm suffered with nervous twitchings, and at the same time the pulse was observed to be much more frequent and feeble than before the spasm. In this condition, it was invariably the case that, if the strychnia were taken immediately after the spasm, the twitchings rapidly disappeared, and the rapid pulse became slower and fuller; but when the remedy was omitted the nervous and depressed condition continued much longer. Beside the medicines already mentioned, the patient drank freely, during his entire illness, of a decoction of *Scutellaria lateriflora*.

"He commenced the use of brandy punch on the second day of the disease; and on the third and fourth days, used each day one quart without showing any symptoms of intoxication, but during the fifth day he could not be prevailed on to take even one-half this quantity. During the first part of the illness he ate and slept well; but during the latter part he took less food and had much less sleep."

"The profuse diaphoresis, which has been previously mentioned, I think may have had a beneficial effect, and I find on examination an article written forty-six years ago, entitled "Proposal to employ Heated Air in Hydrophobia," in which appears the following recommendation.

"It is my wish to propose, through you, to the public, that future cases of this disease may be submitted to the full influence of highly heated air, so as to produce from the skin and lungs a copious exhalation. This treatment affords to my mind a hope of success, because in all the more virulent and manifestly contagious diseases, as plague, small-pox, measles, and scarlatina, there is an effort to throw off the poison by cuticular action; and, in the plague, those who get bubo and cuticular disease early do for the most part recover, and in some instances *spontaneous sweating has appeared to carry off the disease*."

"I will only say, in concluding the report of this case, that I am now fully satisfied that the diagnosis of the disease made during the illness of the patient is correct, even without the aid of a *post mortem* examination; and were I to assume the responsibility

of managing a case of rabies to-day, I should not materially change the treatment from that followed in this case."

In a letter to Dr. Watson, Dr. Flint says:

"The symptoms at, and prior to, my visit, are consistent with the supposition that the patient was in the primary stage of rabies; and, as it seems to me, we were fully justified in having the opinion which we both held at that time. Under the same circumstances I should again form the same opinion. The subsequent history shows the absence of the symptom which is generally a marked feature, and from which the term hydrophobia derives its significance, namely, laryngeal spasm excited by the effort to drink water, and consequent apprehension in making this effort. But I suppose it to be undoubtedly true that this symptom is not invariably present in cases of rabies. While, therefore, hydrophobic manifestations would have been valuable in a diagnostic point of view, their absence is not proof that the disease was not rabies."

"Lyssaphobia may certainly be excluded. The patient appeared to be resolute in the belief that he had no serious affection. There is no ground to suppose that the phenomena were hysterical."

"The character of the convulsive paroxysms is of great importance with reference to the diagnosis. The point of inquiry here is, were these paroxysms due to the strychnia? From your description they were not of the character which strychnia would produce, and the doses of strychnia were not sufficient to produce convulsive movements with disturbance of respiration."

"The fact of recovery naturally excites scepticism in respect of the diagnosis of rabies. I am conscious of this in my own mind. Excluding, however, lyssaphobia, hysteria, and the toxic effects of strychnia, it is difficult to say what the disease was, if it were not rabies. To say the least the supposition that the disease was due to the virus of rabies is not without the range of probability; and the case would, therefore, lead to the employment of the woorara in cases which admit of no doubt as to the diagnosis. Whether the disease was or was not rabies, the effect of the woorara appeared to be useful; and as a contribution to our at present limited knowledge of the therapeutical use of this remedy, the report of your case is interesting and valuable. It is hardly necessary to add, that should the woorara be found to have a curative power in rabies, you will have conferred a great benefit on medicine and on humanity by venturing upon its use, and by the publication of your report."

MATHIEU AND URBAIN ON THE COAGULATION OF THE BLOOD AND OF THE PRINCIPAL ALBUMINOID SUBSTANCES.*

The coagulation of fibrine, myosine, albumine, and caseine are studied separately by MM. E. Mathieu and V. Urbain. Their principal conclusions are as follows.

The fibrine of the blood is in the plasma in a state of solution. It is converted into an insoluble product by being chemically precipitated. This is a result of the combination of the fibrine with carbonic acid, but in order that the acid gas should exercise its coagulating action on the fibrine it is necessary

that it be free. In physiological conditions it is fixed to the hæmoglobine of the red blood-corpuscles, whose function it is to carry oxygen to the tissues and to bring back carbonic acid. If injury or disease produce excess of carbonic acid, or set free that which is normally combined with the blood-corpuscles, coagulation takes place.

After having established by a series of analyses that the proportion of carbonic acid of the blood decreases during the formation of the clot and that coagulation is independent of oxygen, the authors endeavour to prove that the coagulation of the blood is produced by the presence of the acid gas, by showing that blood which has been deprived of carbonic acid becomes incoagulable, and on the other hand that blood thus modified becomes again coagulable, if the carbonic acid which it has lost be given back to it.

There are three conditions in which the acid is set free in the plasma.

1. *Coagulation by Displacement.*—It is by gaseous displacement that blood removed from the vessels and exposed to the air coagulates. In this case the hæmoglobine absorbs oxygen, which gradually displaces the carbonic acid that is combined with the red corpuscles and sets it free. The acid gas then spreads itself through the plasma, and transforms the fibrine in solution into insoluble fibrine. The coagulation takes place at the exact time when the quantity of carbonic acid introduced into the plasma becomes too considerable to be fixed as bicarbonate. This gaseous displacement is analogous to that which takes place during respiration, with the sole difference that during respiration the displaced gas traverses an animal membrane and is eliminated, whilst in the other case it accumulates in the plasma, until it combines with the dissolved fibrine.

2. *Coagulation by Saturation.*—When the elimination of the carbonic acid fixed to the blood-corpuscles cannot take place normally, there comes a time when, their affinity being satisfied, the excess of gas produced *in situ* becomes free in the plasma and consequently is in a condition to exert its action on the fibrine. The formation of clots in pulmonary apoplexy is thus explained. Such also is the mechanism of the coagulation of the blood which follows the ligature of a vessel, and in consequence of inflammation or extreme stagnation of the blood-current.

3. *Coagulation by Change in the Blood-Corpuscles.* This mode of coagulation is the result of a functional diminution of the number of corpuscles, and of an imperfect elimination of the acid gas secreted by the organism. The altered red corpuscles can no longer fulfil their function, the carbonic acid in excess becomes free in the plasma and a clot forms. The coagulations which take place in cutaneous asphyxia and in the course of different cachexies, are the consequence of anatomical and functional changes and numerical diminution of the red corpuscles, and belong to this third class.

Myosine is believed by physiologists to be a simple variety of fibrine, and the experiments of MM. Mathieu and Urbain show that the mechanism of the coagulation of those two substances is perfectly analogous. Muscular rigidity is the result of coagulation of myosine; it is preceded by slow oxydation of the tissues which produce carbonic acid. During life, the carbonic acid produced by the organic oxydations is unceasingly carried off by the blood-corpuscles and eliminated by respiration and

the secretions. But after death, this elimination no longer taking place, the carbonic acid accumulates in the tissues, and provokes coagulation of the myosine and in consequence muscular rigidity, which can take place either in acid or alkaline tissues, for the acidity due to lactic acid and muscular coagulation are only a simple coincidence without the relation of cause and effect.

The general result of their researches is thus summed up. 'The transformation of a soluble substance into an insoluble compound is produced by the intervention of an acid, usually masked by the alkalinity of the fluid. This acid, indispensable to the formation of a clot, pre-exists neither in milk, nor in muscle, nor even in the normal fluids of the organism, the blood excepted. On the contrary, the acid which coagulates fibrine and albuminous fluids properly so called, pre-exists in the blood, the white of egg and the fluids of the normal or pathological secretions of the economy.'

G. THIN, M.D.

ANATOMY AND PHYSIOLOGY.

KÜHNE AND GRUTZNER ON ORGANISED AND SO-CALLED AMORPHOUS FERMENTS AND ON TRYPSIN (EUZYM OF THE PANCREAS).—W. Kühne (*Verhandlungen der Naturhistorische Verein zu Heidelberg*, Neue Folge, Band i. p. 194, and *Centralblatt für die Medicinischen Wissenschaften*, no. 36) proposes to call the amorphous ferment euzym, the ferment of the pancreas, trypsin. Its action is not arrested by salicylic acid, and this substance is very applicable for demonstrating the specific digestive actions of the pancreas from other actions, such as putrefaction, which may occur simultaneously. Eight hundred grammes of pancreas of ox treated with four grammes of salicylic acid and two litres of water at 40° Cent. (102° Fahr.) showed no bacteria, no smell of indol, whilst the glands were dissolved after several hours. Filtered portions digested powerfully. Sulphuric acid and hydrochloric acid in equal quantity did not produce the same effect, but acetic acid did so in a striking manner. Salicylic acid does not affect the action of pepsin, but rather protects its solutions from putrefaction. Pepsin destroys the action of trypsin, but the pancreas ferment does not affect pepsin, but this latter is rendered inactive by an alkaline reaction. The explanation offered by Kühne of the increased appetite of dogs with biliary fistula is, that normally the pepsin is destroyed by the bile. If the bile be not poured out, the pepsin, still active, passes into the duodenum, and disturbs the pancreatic digestion.

According to Heidenhain, the pancreas contains only zymogen. If, however, according to Kühne, a pancreas quite fresh and still warm be rubbed up with absolute alcohol, and from the gland so treated, a watery extract be prepared at 0° C. (32° Fahr.), this extract is at once active. Heidenhain's zymogen is therefore a body capable of being split up by alcohol. If the extract of the gland be repeatedly precipitated by alcohol and dissolved in water, and if to the watery solution acetic acid be added to 1 per cent., then an albuminous body is precipitated, which the author terms leukoid, whilst the filtrate again precipitated by alcohol yields a precipitate essentially consisting of trypsin. Trypsin is amorphous, transparent, of a feeble straw-yellow colour, easily soluble

in water. The solution, even when rendered alkaline, can be kept unchanged, no formation of peptones, leucin, or tyrosin taking place. On being boiled, it is decomposed into coagulable albumen and peptone. In watery solution trypsin dissolves fibrin when warmed almost at once; the solution contains peptone, antipeptone, leucin, and tyrosin. The process is this: first peptone is formed, which is not to be distinguished from that formed in the stomach, and that this now produces antipeptone and the other substances, which are chiefly products of decomposition and crystalline.

Trypsin has no action on starch and dextrin; putrid albumen and bacteria contain no trypsin, and, in fact, no ferment which resists the action of alcohol. No trypsin is to be found in arterial blood, the salivary glands, and lymph gland of the mesentery.

P. Grutznar (*Pflüger's Archiv*, Band xii. p. 285), has also made some observations on the amorphous ferments.

1. The salivary glands of the dog, according to this author, do not form any sugar-ferment. It is true that, with long digestion of the mixed saliva or the glycerine extract of the glands with starch-mucilage, a saccharine reaction is obtained; such traces of a diastatic ferment, however, are found in all parts of the body. The salivary glands of man and of the vegetable feeders undoubtedly contain a diastatic ferment; in the rabbit the parotid is much richer in ferment than the submaxillary gland.

2. The use of Brunner's glands in the wall of the intestine has long been doubtful. The author finds that their gland-cells are microscopically not to be distinguished from those of the pyloric glands; in fact, by extracting them with glycerine or hydrochloride of 1 per cent., an extract containing pepsin may be obtained, which is richer in pepsin when the cells are large and clear than when they appear turbid. Whether the ferment secreted by these glands is active during life is, from the alkaline reaction in the intestine, doubtful. No diastatic ferment was to be detected in Brunner's glands.

3. The amount of the diastatic ferment in the pancreas varies with the time which has elapsed since the last meal. It is least six hours after food, and greatest fourteen hours thereafter. The quantity of the ferment was estimated by the action of the glycerine extract (10 grammes fresh pancreas and 100 grammes glycerine) on starch-mucilage, analogous to the method of Grünhagen for estimating the amount of pepsin. The starch-mucilage was placed in a filter, and was treated with an equal amount of the glycerine extract (0.3 gramme); the quantity of the filtrate produced in a given time gave the measure of the activity of the extract. The first filtrates produced by the action of the diastatic ferment were rich in erythro-dextrin (Brücke), poor in sugar, whilst the later contained much more sugar. Further experiments led to the general result, that the products vary according to the intensity of the action of the ferment. The smaller the amount of ferment and the shorter its action, the greater the prevalence of the dextrin; in the opposite case, the sugar. The same is true for pepsin. With a small amount of the ferment, short time of action, etc., syntonine is the chief product formed; in other cases, peptone. The addition of 0.5 to 1 per cent. of carbonate of soda arrests the action of pepsin. In both cases, the intermediate products dextrin and syntonine (parapepton) are chiefly formed. These observations, together with

many others, prove that the amorphous ferments are destroyed during their action. The pancreas-ferment which acts upon the fats presented great difficulties in its investigation. It is very unstable in its nature. The glycerine extracts of the pancreas gradually become acid, and as soon as this takes place the fat decomposing action ceases. Later, the author employed a feebly alkaline glycerine. The glands were poorest in fat ferment six hours after an ample meal, and the quantity rose till the fortieth hour. The fat-ferment is only active in an alkaline or neutral solution. Even the salivary glands yield far more active extracts when they have been exposed for some time to the air, than when they are prepared quite fresh. Similar observations have been made by Liversidge and Heidenhain for the pancreas; by Von Wittich, Ebstein and Müller for the liver; and by Hammarsten for the ferment of the stomach.

MAYER AND FRIEDRICH ON THE PHYSIOLOGICAL ACTION OF NITRITE OF AMYL.—S. Mayer and J. Friedrich (*Arch. für exper. Path.*, Band v. p. 55, and *Centralblatt für die Medicin. Wissenschaften*, no. 38), in order to avoid the disturbing effects produced by inhaling this drug through the nose, invariably administered it through a tracheal cannula; and according to the duration of inhalation of the vapour, they distinguished a weak (4–60 sec.) or a strong dose (over a minute). These observers, like Filehne, always observed a considerable increase in the frequency of the pulse produced by the amyl-nitrite. In the explanation of this phenomenon they also agree with Filehne, in ascribing it to a diminution of the tonus of the vagus-centre, and adduce several new facts in support thereof. In dogs, which have received amyl-nitrite, the difference in the number of beats during inspiration and expiration disappears; further, if in curarised animals, when by stopping the artificial respiration, the number of heart-beats has been reduced in consequence of stimulation of the vagus-centre by the dyspnoic blood, a small quantity of amyl-nitrite be injected into the jugular vein, the frequency of the heart-beats increases just as if the vagi were divided. Large doses of amyl-nitrite paralyse the heart itself.

Regarding the fall in blood-pressure produced by amyl-nitrite, the authors have succeeded in affording a new proof of the view of Lauder Brunton, that this drug acts directly on the walls of the vessels. After the method of Kussmaul and Tenner, by cutting off the supply of blood to the brain and medulla oblongata, they rendered these organs inactive, so that all phenomena depending upon these centres ceased. If amyl-nitrite were now inspired, the blood-pressure fell considerably.

After moderate doses the respiration became more frequent and deeper; after strong doses, flat and very slow. In this case, it is due to a direct action on the respiratory centre. That the change in the blood-circulation does not produce the dyspnoic respiration, is proved by an experiment with diminution of the blood-pressure by stimulating the nervi depressores. In this case acceleration of the respiration only occurs here and there, although the diminution of the blood-pressure is greater than that produced by the amyl-nitrite.

The spasms produced by this drug are not caused by the changes in the circulation, but are due to a direct stimulation of the brain. The spinal cord does not appear to be influenced thereby.

After inspiring the vapour for a considerable time,

the animals pass into a condition where the blood-pressure falls very low, the heart-beats and the respiratory movements are slow but regular, and the peripheral nerves and the muscles remain excitable. As this stage lasts for a long time (one hour), it may probably be of value for some experiments.

SCHWALBE ON THE NUCLEI OF GANGLIONIC CELLS.—Professor G. Schwalbe (*Festschrift für Naturw.* Band x.), remarks that, if a perfectly fresh and completely transparent retina of a sheep be spread out in aqueous humour, with its inner surface upwards, on an object-glass, it is easy to detect, in the parts lying next the ora serrata, the ganglionic cells sharply defined, as here the nerve-fibres are reduced to sparsely scattered bundles. Round bright spots, just like fluid in a cavity, are to be observed in a dimly glancing homogeneous mass. On more exact observation, a round nucleus is to be detected within each bright spot, with all the characters of a nucleus of a ganglionic cell. The remaining part of the space is clear, with the exception of a small amount of a finely granular substance around the nucleus. On adding iodised serum, the whole transparent space becomes turbid and appears finely granular. As an argument against the supposition that the granular layer is nervous, the author cites the completely different optical properties of fresh ganglionic cells and fresh granular substance. The latter appears as if it were permeated by innumerable small vacuoles. The shining homogeneous substance between the ganglion-cells shows no trace of tissue-elements, and is obviously comparable to the cement-substance of epithelium. The nuclei of the ganglion-cells of the retina possess a membrane, whose inner surface is provided with fine projections. Sometimes they contain a toothed nucleolus provided with fine processes. In adult animals the difference in size in the ganglionic cells is comparatively trifling. In young animals (calf), however, it is extraordinarily great, and the same is true of the nuclei. The smallest nuclei are the youngest. They are without trace of nucleolus, and consist of a regularly distributed granular mass. No differentiation into nuclear membrane and contents is present. The substance, out of which the nuclear membrane and the nucleoli are ultimately formed, is at first regularly distributed through the whole nucleus and completely fills it, and is permeated by numerous small vacuoles filled with another mass. During the growth of the nucleus, the vacuole-substance increases without any essential increase of the other constituents of the nucleus being visible. The consequence of this is, that the latter is torn into several portions, of which one always encloses the surface of the nucleus, and becomes the so-called nuclear membrane, with a number of irregular projections; the nucleoli adjacent to the wall projecting into the interior of the nucleus, whilst other portions roll themselves together into one or more nucleoli. In proportion as the clear substance in the interior of the nucleus increases, the internal projections of the nuclear membrane in consequence of the extension of the latter, are caused more and more to disappear. The whole process may be regarded as one of vacuolation, similar to what occurs in plant-cells, in the separation of protoplasm from the cell-juice. In ganglion-cells in other localities (anterior horn of the spinal cord in the rabbit and pig, ganglion Gasserii of rabbit, spinal and sympathetic ganglia of frog) the nuclear membrane is absent, and therewith the

nucleoli adherent to the wall (*i.e.* thickenings on the interior of the membrane). The clear juice of the nucleus with vacuolated nucleolus adjoins the cell-substance directly.

These observations of Schwalbe contradict the results of Auerbach, that the nucleoli wander from the protoplasm of the cell into the nucleus. According to Schwalbe, these arise like the nuclear membrane from the original nuclear substance; in that the latter, by the accumulation and increase of the clear nuclear juice, is broken up into several pieces. Further, no increase of the nuclear substance takes place; this remains constant, and during increase of the nucleus diminishes relatively. Thus it arises that, in ganglion-cells, in opposition to the results of Auerbach for other cell-nuclei, one observes a plurinucleolar condition preceding the uninucleolar, and that the latter may pass into a non-nucleolar condition, in which the entire nucleolar substance is employed as nuclear membrane. The author arrives at the conclusion that Auerbach's results on the origin and increase of nucleoli are not to be generalised.

In the body of the spinal ganglion-cells of the frog, two substances are to be found; one of which forms a very delicate network, which reaches from the surface of the membraneless nucleus to the surface of the cell; whilst the other, the clearer, fills the meshes. The substance of the nucleolus is optically different from these two substances, whilst the nuclear juice appears to be identical with the mass filling the meshwork. There are therefore three substances to be distinguished in the ganglion cells—the nucleolar substance, the cell-juice, and the reticular substance. The view of Max Schultze's regarding the fibrillar condition of the nerve-cell, according to Schwalbe, depends upon an imperfect interpretation of the reticular substance. Lastly, the author remarks regarding the difference in structure in nerve-cells of different localities.

LEWIS ON A NEW METHOD OF STAINING THE FRESH BRAIN.—In the September issue of the *Monthly Microscopical Journal*, Dr. Bevan Lewis, Pathologist to the West Riding Asylum, publishes a paper on the preparation and staining of fresh brain for microscopic examination.

After commenting on the importance of examining brain at the earliest possible opportunity for the determination of pathological states, Dr. Lewis goes on to speak of the relative value of the older methods of hardening by chromic acid and its salts, and the fresh method which he recommends, indicating at the same time the necessity of employing both under certain conditions. After referring to the plan adopted by Dr. Batty Tuke, and more recently by Mr. Sankey, the writer describes his method as embraced in three stages—namely, first, preparatory; secondly, staining and differentiation; and thirdly, permanent mounting of the preparation.

In the first stage, a fine vertical section of the cortex is transferred to a slide bathed in Müller's fluid, a glass cover placed over it, and gentle steady pressure exerted until an almost transparent film is obtained. The slide is transferred to methylated spirit for twenty to thirty seconds, by which time the cover can be readily removed; the superfluous spirit is then removed. The object of these measures is the production of a film of uniform thickness, and little or no friability.

In the second stage, the film is treated with

aniline black, the staining being favoured by immersion in water.

In the description of the third stage, the various modes of drying this film are considered, preference being given to drying spontaneously under a bell-glass enclosing a little concentrated sulphuric acid to hasten the progress. When perfectly dry, a few drops of chloroform are placed on the film; and before evaporation, permanent mounting is carried on with a chloroform or benzole solution of balsam. The rationale of this process is then dealt with; the term crushing, as applied to it, is objected to, as the elastic nature of the neuroglia probably suffices to explain the great immunity of the cells and processes from any injury, tearing, or distortion, thus rendering the method equivalent to the most delicate teasing. Accompanying the paper are two plates showing sections from the ascending frontal convolution of the human brain, magnified 50 and 210 diameters respectively, which exhibit the larger and smaller pyramidal cells, and other details of the cortex. A brief reference is next made to a very valuable modification of the old process of hardening and section-cutting, whereby the cells are exposed, in their most recent and active state, to the action of the staining simultaneously with the hardening reagents.

WM. STIRLING, D.Sc., M.D.

FOSTER AND DEW-SMITH ON THE EFFECTS OF THE CONSTANT CURRENT ON THE HEART.—Dr. M. Foster and Mr. A. G. Dew-Smith (*Journal of Anatomy and Physiology*, vol. x. part 4), give the result of investigations on the effects of the constant current on the heart. The animals used were chiefly frogs and toads, but also a few tortoises and dog-fishes. The current was applied by means of non-polarisable electrodes, and tracings of the heart's beats were obtained by using a light lever.

When a weak current was passed from apex to base of the lower two-thirds of the ventricle, or *vice versa*, either 1, no effect was produced, or 2, a beat was obtained at the making or breaking of the current, or at both, but during its passage there was perfect quiescence. Generally the making beat proceeded from the cathode towards the anode, and the breaking beat from the anode towards the cathode. Thus far, the cardiac tissue was in keeping with Pflüger's well-known law. But stronger currents produced rhythmic pulsations on the making of the current, which continued during its passage—the previous quiescent period—and ceased when it was broken. These rhythmic pulsations increased in number as the current increased in intensity; but however strong the current, it was impossible to develop a complete tetanic condition, such as occurs in ordinary striated muscle.

Such rhythmic pulsations had been already noticed by Eckhard, and were considered as a particular instance of the tetanus seen in an ordinary muscle-nerve, to which the constant current had been applied. Dr. Foster and Mr. Dew-Smith believe, however, that the rhythmic pulsation obtained is entirely different from such a tetanic condition, and, on the supposition that ganglionic cells are absent from the part of the ventricle they used—the lower two thirds—hold that such pulsations can only be explained on the hypothesis that the cardiac muscle has not entirely lost that power of rhythmic contraction resident in primitive protoplasm.

They next point out that, according to the size of the piece of ventricle employed, there was always

one special direction in which the current had to be thrown, in order to get the rhythmic pulsation most readily, *i.e.* according as one part or another was made cathodic. After giving an explanation of this, *viz.*, that it is most probably connected with the predominance of the catelectrotonic phase, they go on to consider the interesting point, that when by means of a current rhythmic pulsation is set up, the break beat is absent. They further consider the effect of the current on the whole ventricle when quiescent, or when beating spontaneously, and on the ventricles and auricles beating spontaneously and with the cavities distended with serum or not. The results obtained in these instances resembled the former, but were not so definite. One curious point was that, when the heart was *in situ*, and the circulation intact, even a strong current had little or no effect. The effects of a constant current on the heart brought to a standstill by Stannius' experiment, or by stimulation of the vagus, are lastly considered. In the latter case the constant current produced no evident effect, but when the current was passed and the vagus stimulated, inhibition took place apparently as usual.

From all these experiments, they conclude that all rhythmic pulsations are due to the action of the constant current on the muscular tissue of the heart; further, they believe that the vagus, when stimulated, acts like any other nerve on the muscular tissue of the heart itself. The ganglia, they therefore think, play an unimportant part in the production of the heart's spontaneous rhythmic pulsations; and they hold that the vagus, when stimulated, does not inhibit the heart's action through the ganglia, but by influencing directly the cardiac muscle.

J. C. EWART, M.B.

PATHOLOGY.

BURGL ON TRANSPOSITION OF VISCERA.—Nos. 24 and 25 of the (Munich) *Aerztliches Intelligenz-Blatt* for June 13 and 20, 1876, contain two papers by Dr. Georg Burgl, of Munich, on the subject of Ectopia or transposition of viscera, entitled 'Zur Casuistik des Situs Viscerum mutatus.' He commences with a bibliography, and then proceeds to detail four cases which have lately come under his own observation.

1. The first case is that of a woman dying in the Munich Hospital. The peculiarities named were discovered in the dissecting-room, whither the unclaimed body was taken. The heart was on the right side (dextro-cardia), and the abdominal viscera were transposed. The right ventricle of the heart was hypertrophied, and gave origin to the aorta, whilst the pulmonary artery took its origin from the left ventricle. The innominate artery was the first branch on the left side of the aortic arch, and divided into a left carotid, and subclavian. Both *venæ cavae* discharged their blood into the left auricle. The right lung had two, the left three lobes. The oesophagus lay on the right side. Left-sided hydrothorax, and compression of the lung, were found. The liver (which was nutmeg-like) was in the left hypochondrium. Its larger lobe occupied the left side, the lesser lay over the stomach, and pushed the spleen to the right. The spleen, indeed, was found in the right hypochondriac region. The stomach lay with its fundus to the right, and its greater curvature to the right and below. The duodenum lay on the left,

the ascending colon in the left iliac and lumbar region; the descending colon on the right side; the cæcum on the left; the rectum right. There is a photograph of this case in Rüdinger's 'Topographical and Surgical Anatomy.'

2. The description of the second case is by Professor Von Ziemssen, though the diagnosis was made before the patient was admitted to the hospital.

Magdalena Eilles, the daughter of a day-labourer of Haidhausen, aged twelve, was admitted to the hospital April 3, 1876. The cyanosis was not much noticed till she was six years of age. She was an intelligent child, but had suffered lately from oedema of the feet, symptoms of syncope, vertigo, and other signs of disordered circulation. She had had scarlatina and diphtheria. Her digestion was fairly good, and the bowels regular. There were two living of the same family, apparently with normal viscera—one brother and one sister. Three sisters were born dead. The father died six years ago of meningitis, and had been ill long before his death. It did not appear, however, that his heart was affected, or his viscera transposed. Her state on admission was extreme cyanosis, she had very clubbed fingers. Pulse 104; respirations 32. She was in height 55 inches, and weighed about 58 pounds. The heart was on the right side of the chest. Its apex-beat was in the right thorax, midway between the lines of the nipple and of the right axilla, about $1\frac{1}{2}$ inches outside the nipple line, in the fifth costal interspace. The cardiac dulness began at the third rib, and was 4 inches in the diagonal line by $3\frac{1}{4}$ at its base. There was a faint systolic murmur heard on the right of the sternum between the third and fourth ribs, and best at the third rib. There was no venous pulsation. The physical signs indicated the liver to be on the left, and the spleen on the right. The injection of an effervescing enema distended the ileo-cæcal region first, and the distension remained greatest here. The apex of the lung on the left side seemed to be a little lower than the right. The girl was undoubtedly right-handed. From a combination of physical signs and symptoms, the diagnosis was made as follows: Transposition of the thoracic viscera, also of the abdominal viscera; stenosis of the pulmonary artery, and permanent opening in the septum ventriculorum (*sic*).

3. Anton Wimpensinger, aged fifteen, a book-binder's apprentice, had always been healthy as a child. He was admitted to the hospital for difficulty of breathing felt for a few months only. He was rather diminutive. Respiration was somewhat stridulous.

The apex of the heart was felt and seen in the fourth and fifth intercostal spaces on the right side, best in the fourth. Cardiac dulness reached from the line of the right nipple to the right edge of the sternum, and above to the third rib. Over the pulmonary artery (on the right side of the sternum) a weak systolic bruit was heard, and a slapping second sound. The spleen was of apparently normal size on the right side. The liver was on the left. Somewhat large distension of the stomach with carbonic acid showed that its fundus was on the right, and the pylorus on the left. Distension of the rectum showed itself first in the right ileo-cæcal region, and revealed that the rectum, sigmoid flexure, and descending colon were on the right. As the parents were dead, their anatomy was unknown

The lad was decidedly right-handed. (This description also is by Professor Ziemssen.)

4. Peter Hundsrucker, aged twenty-seven, day-labourer, attended the Hospital on December 27, 1875, complaining of cough and dyspnoea. Until 1870 he was always healthy. Then he had dysentery at Nancy. He was invalided eight days at Bazeilles by a shot grazing his shin. In October, 1872, he had articular rheumatism, and suffered more or less for a year. In the autumn of 1872, he remarked blood in a vomit. This has happened once or twice since. The father died at sixty, of some unknown disease. The mother, aged seventy, and sisters were healthy. There was no cardiac dulness on the left. There was pulsation to be seen on the right side in the second, third, and fourth intercostal spaces. It could be easily felt in the fourth space. In the right parasternal line, and at the edge of the sternum on the right side, there was dulness beginning at the third rib and reaching almost to the right nipple. The (apparently normal) cardiac sounds were heard on the right side instead of the left. Physical examination of the thorax and abdomen led to the following diagnosis: Transposition of the thoracic viscera; the same of the abdominal organs; pleuritic effusion on the left side; phthisis, and syphilis. Although the pleural exudation seemed to render the case a little doubtful at the first moment, it was not so to those who watched it from day to day. The author expresses his thanks to Dr. von Ziemssen and Dr. von Buhl for their kind assistance in the examination, and reports of these cases, to the former for the last three, to the latter for the first case reported.

Bibliography.—The translator has selected the following from the original papers.

The first recorded case of transposition is said to have been in 1648, in a new born child in Brittany [Riolanus, 'Opuscula Anatomica, varia et nova.' Parisiis, 1652, pag. 133.] At p. 117 of the same work, another case, Morand and Mery [*Mémoires de l'Académie Royale des Sciences*, 1666-1699, tom. x. Paris, 1730] see also Bernard Schultze, Virchow's *Archiv*, Bd. xxii. p. 210. Geoffrey St. Hilaire's 'Histoire générale et particulière des Anomalies,' etc., tom. ii. Paris, 1836, contains fifty such cases.] Wenzel Gruber in Dubois-Reymond and Reichert's *Archiv*, 1865, reports seventy-nine such cases up to date.

The following works on the subject in the present century up to 1865, have been mostly collected by Wenzel Gruber:—Von Siebold, F. M. Heiland, 'Darstellung des Verhältnisses zwischen der rechten und linken Hälfte des menschlichen Körpers,' Nürnberg, 1807, p. 55. Sampson, *Philosoph. Transact.*, vol. ix. Béclard, *Bullet. de la Fac. de Méd.*, December 12, 1816. Rostak, *Nouveau Journal de Médecine*, May, 1818. Krupp, 1820, *Journal Général*. Scouteten, Forriep's 'Notizen aus dem Gebiete der Natur- und Heilkunde,' Bd. vi., Nr. 8. Wette, 'De situ viscerum inverso,' Diss. Berlin, 1827. Baer C. E. von, 'Ueber Entwicklungsgeschichte der Thiere,' Königsberg, 1828. Bujalsky, 'Beschreibung einer umgekehrten Lage des Herzens, etc., mit Mangel der Milz,' Petersburg, 1829. John Alexander, *Lond. Med. Gaz.*, November 22, 1834. Grisolles, *Bullet. de la soc. anatom.*, 1834. H. M. Leppington (*vide* Schmidt's *Jahrbücher*, 1835). Pétrequin, *Gaz. méd.*, April 1, 1837. Gery, *Archives Générales de Médecine*, 4 série, tome i., 1843. Bichat, 'Anatom. descript.,' 1846. Boss, *Bullet. de la soc. anat. de Paris*, 1846. Buehring, 'Die seitliche Rückgratsverkrümmung,' Berlin,

1851. Stolz, *Gaz. méd. de Strassbourg*, 1851. Vel-ing, *Gaz. méd. de Strassbourg*, 1854, v. i. Virchow (Würzburg, 1854, Ein von Virchow beobachteter Fall von einem Typhuskranken. Das Präparat befindet sich in der patholog. Sammlung zu Würzburg.) Luys, *Gaz. méd. de Paris*, Tom xi., 1856. Günzburg, 1856, Breslau, 'Studien zur speciellen Pathologie,' vol. ii. Werdmüller, *Schweizer Zeitschrift für Medizin*, 1856, Heft 3. Bouvier, *Leçons cliniques sur les maladies chroniques de l'appareil locomotrice*, Paris, 1858. Remak, Robert, 'Untersuchungen über die Entwicklung der Wirbelthiere,' Taf. III., Fig. 49. Schultze, Virchow's *Archiv für path. Anatomie, Physiologie*, etc., Band xxii. Neugebauer, Nägele's *Geburts-hilfe*, Mainz, 1863. Förster, Aug., 'Die Missbildungen des Menschen,' Jena, 1865. Hyrtl's 'Topo-graphische Anatomie.'

Dr. Burgl also refers to the cases reported by Dr. Scheele (see the *Berliner Klinische Wochenschrift*, for July 12 and 19, 1875), and gives the bibliography appended to Dr. Scheele's cases (see LONDON MEDICAL RECORD, Sept. 15, 1875.) He also appends the following remark. Guttman considers these malformations as most common in the male sex. There are now several cases on record in which malformed parents have had well formed children, and there are others of hereditary transmission. The remainder of the paper is taken up with a discussion of the mode in which these transpositions may occur in the embryo. There is little of novelty to those who are familiar with Von Baer's and Rindfleisch's writings. Hyrtl is quoted as an authority for the non-transmission of such defects, and so is Schultze. In the original paper, the four new cases are reported at great length. W. BATHURST WOODMAN.

COLIN ON DIAPEDESIS OF LEUCOCYTES IN MAN. M. Colin (*Archives de Médecine*, December, 1875), finds in the melanotic deposits, which are found in malarial poisoning, a proof of the diapedesis of leucocytes in man. He does not believe that the pigment-deposit found external to the vessels and within the substance of their walls is the result of the decomposition of the red corpuscles *in loco*. The pigment in both instances has its origin in granules, which were first contained in the circulating blood, and were finally extravasated. The mechanism of the extravasation is found in the white corpuscles, which become charged with the pigment and then pass out of the vessels.

This diapedesis is present in health, but is not evident, as the corpuscles do not then contain pigment.

WEIGERT ON LESIONS IN PARENCHYMATOUS ORGANS IN SMALL-POX.—Weigert (Breslau, 1875), describes in the viscera, in cases of variola, small circumscribed nodules enclosing cellular masses, which he believes to be analogous to the pustules of the skin. He has found them in the liver, spleen, kidneys, and lymphatic glands. They consist of a well-defined wall enclosing a granular mass. In many places they are enclosed by a membrane, sometimes nucleated, which perfectly resembles the wall of a blood-vessel. In the kidney and liver, they are found in the vessels. In the kidney they are present in the glomeruli, and (not so frequently) in the medullary substances. In the liver they are found more frequently in the parenchyma than in the capsule. Except in the glomeruli, they are not found in the arteries properly so-called, occupying on the other hand the capillaries and small veins.

[The author is one of those who believe that bacteria produce such results as those which he has described.]

TAMASSIA ON THE CHANGES THAT TAKE PLACE IN PUTREFYING TISSUES.—The author's studies (*Rivista Sperimentale di Freniatria e di Medicina Legale*, 1875), relate especially to muscle and tendon, his object being to study from day to day the modifications produced in the normal structure of the putrefaction of tissue. With this view, he allowed fragments of muscles and tendons to putrefy in air, in water, in the soil, and in urine, and noted daily the changes which he observed.

The principal results described are as follows. When putrefaction begins, the muscular fibre swells, its substance becomes opaque and yellowish. After the fourth day, if the muscle have been exposed to the atmosphere or have been in the soil or water, and after the third day, if it have been in urine, there form within the sarcolemma yellow, highly refractive irregularly discoid granules, insoluble in ether and chloroform, and appearing to be derived from the albuminoid substances of the muscle, and more especially from the sarcous elements. Later, these granules break up into fragments, and become extremely fine. The complete disappearance of all contractile substance takes place in water about the forty-second day, in the soil about the thirty-sixth or thirty-seventh day, in the atmosphere about the thirty-fourth day, and in urine about the thirtieth day. The sarcolemma becomes opaque, and after the eleventh day in water, the ninth in the soil, the seventh in the atmosphere, and the fifth in urine, it exhibits partial ruptures. It disappears by resolution into very fine opaque granules after eighteen days in water, seventeen in the soil, fifteen in the atmosphere, and thirteen in urine. Tendons resist much longer than muscles. They first begin to change in water on the thirtieth day. They become yellowish and longitudinal striæ divide the substance into finer and finer bundles. This is produced by the substance proper of the tendon resisting putrefaction much longer than the substances which bind the bundles together. As these disappear the tendinous fibrillæ become free. Later, about the forty-fifth day of maceration in water, the fibrillæ become yellowish, break up, and begin to be resolved into a mass of granules. Their disappearance is complete about the seventy-fifth day.

COHNHEIM ON CONGENITAL STRIPED-MUSCLE SARCOMA OF THE KIDNEY.—The kidneys (Virchow's *Archiv*, Bd. lxx.), were from a child which was healthy during the first twelve months after birth, then sickened, and died three months later. Both kidneys were invaded by tumours, which were found on microscopical examination to be composed of striped muscular fibres. The fibres were small, long, and interwoven. A sarcolemma was not discovered. In other parts, but not so plentifully, the typical structure of a sarcoma was found.

This is the first time that these very rare tumours—striped muscle sarcoma—have been found in the parenchyma of the kidney, where their presence constitutes a veritable monstrosity. The fact that both kidneys were affected tends to show, according to Cohnheim, that there was an original faulty growth, and not a metastasis. It is impossible to understand what the histological elements were that formed the point of departure for the muscular fibres.

BOISSIER AND CORNIL ON UNUSUAL DEVELOPMENT OF CARCINOMA.—In the *Bulletin de la Société Anatomique*, (Paris, 3e série, tome x. 1875), a very interesting and rare case is described of 1st carcinoma developed in a new growth; 2nd, carcinoma of a suprarenal capsule, a rare affection.

Clinically there was nothing special; the symptoms were those of abdominal cancer. At the necropsy, the body and cervix of the uterus were displaced, but without any alteration of their tissues.

Two tumours were found, one of which, as large as the head of a foetus at term, was attached to the uterus. Examination of the tumours, by M. Cornil, showed a peripheral layer of smooth muscle enclosing tissue of encephaloid cancer. A similar cancerous production was found on the right suprarenal capsule.

The obscure point in the case is relative to the origin of the cancer. It is impossible to know whether it began in the suprarenal capsule or in the myoma. It is certain that the myomata existed first, and that cancer developed in their interior.

MEDICINE.

BETZ ON A PATIENT WHO WASHED OUT HIS OWN STOMACH.—In Betz's *Memorabilien*, Jahrgang xxi. Heft 4, Dr. Friedrich Betz narrates the following case. The patient, a merchant, who had been a sugar-baker, now forty-nine years of age, had suffered from dyspepsia ever since he was fifteen years old. In the beginning he suffered chiefly from a horrible feeling of hunger, with collections of saliva in his mouth, hiccup, and pyrosis. For some time a milk-diet relieved this. He could never bear smoking, nor fatty or farinaceous food. In the course of time, all these symptoms grew worse, and then he had severe pains in his stomach; then actual vomiting of sour smutty-coloured masses; with obstinate constipation, loss of sleep, etc. For about a year and a-half his condition was a horrible one. The epigastric pain was almost unbearable; he vomited more than he ate; and his strength failed rapidly. After Dr. Betz had satisfied himself by percussion and auscultation that the stomach was dilated, and retained its contents, he proceeded to use the stomach-tube. The contents of the stomach were neutralised and diluted with warm water containing carbonate of soda. Cold water could not be borne. Only the tube was used, not the stomach-pump. The first attempts set up a little pharyngeal and oesophageal irritation, but this soon subsided. In the intervals, anti-fermentative and tonic remedies were used. The diet was restricted as to quantity and quality. The exacerbations were relieved by hypodermic injections of morphia, and cold compresses to the anterior surface of the body, clysters, etc. Sometimes the pain appeared to be due to peritonitis. As he lived too far from Dr. Betz for him personally to use the stomach-

pump, the local surgeon did so ten or twelve times. But one night, the tube being kept in the house, the patient felt so urgent a need to empty his stomach, that he seized the tube, introduced it himself, and filled the funnel with water; then, by simply bending forward, as had been done before, the diluted fluid escaped. For the last five weeks he has had resort to this means, but whether finding that filling the funnel was too slow for him, or too troublesome, he has had recourse to the following plan. He has two or three vessels of hot water, holding nearly a pint each, near him, and drinks one of them. He then introduces the oiled tube, whilst sitting; he then stands up, bends forward the upper half of the body, and lets some of the water run into a basin. Then he drinks the second glass, repeats the manœuvre with the tube, and continues till the fluid comes back clear from the stomach. He takes account how much goes in, and how much comes out. In general the latter exceeds the former. This treatment has done him good; his appetite is better, the bowels are regular, and his strength improved, so that he can walk for an hour comfortably. He takes baths of the Neckar water, and is gaining weight. He is so fond of the tube, that he takes it with him in travelling. He overcomes the difficulty caused by the cricoid cartilage projecting behind, by drawing a deep breath. The introduction of the tube no longer gives him pain. If the lateral openings be stopped up, he simply withdraws the tube, cleanses it and puts it in again. It is an English tube, with an olive-shaped end. It must be well oiled. He thinks, perhaps correctly, that he would not have suffered so much if the tube had been used earlier in his complaint. Dr. Betz proposes to try electricity in this case if the stomach does not show some power of contraction upon its contents in a reasonable time. There is no tumour, but very probably callous thickening of the pyloric end. It is interesting to note how quickly the removal of the acid contents relieves the pain, so that it seems likely that there is a direct irritation of the nerve-terminations in cases of this kind. However, he says the object of his paper is not to describe the pathology of this patient's dyspepsia, but rather its therapeutic technology, 'the remarkable thing,' as the patient calls it, of his success in washing out his own stomach. It may encourage others.

'Sibi quisque inde exemplum expetat.'—PLAUTUS.

ROTHER ON INTERMITTENT DIARRHŒA.—In Betz's *Memorabilien*, Jahrgang xxi., Heft 4, Dr. C. G. Rothe, of Altenburg, writes that, during the sixteen years in which he has practised there, he has repeatedly met with cases of diarrhœa, accompanied with severe colicky pains, which have proved rebellious to ordinary therapeutic measures, and were marked by a striking periodicity. Lastly, they were rapidly cured by quinine. Two such cases which occurred lately may serve as examples.

1. Mrs. Brauer, aged twenty-five, a labourer's wife, of stout build, and always healthy, consulted Dr. Rothe on September 13 last, on account of diarrhœa with acute pains in the abdomen, resembling labour-pains. Her general health was but slightly affected, her appetite fairly good, so that she was able to do her household work without interruption. Looking on it as an ordinary case of catarrh of the intestines, Dr. Rothe ordered, empirically, an iodised carbolio acid mixture, and regulated diet; but three days

brought no improvement. He then ordered acetate of lead, with rhubarb and opium, of the latter 3 centigrammes every three hours ($\frac{3}{4}$ grain nearly), and ordered her to keep in bed. After another three days, she was rather worse than better. There was no particular tenderness on pressure, and the tongue was not much furred. On closer questioning, however, he learnt that the patient felt pretty well all day long, until about 7 o'clock in the evening, when she was regularly attacked with severe colic, followed by liquid stools, and again had an interval free from pain and diarrhoea till the next evening. Remembering former experiences, he now ordered 1·2 gramme of sulphate of quinine (about $18\frac{1}{2}$ grains) divided into four doses, one to be taken every three hours. Next morning the patient had had a quiet night, free from pain and diarrhoea, and she remained free from them afterwards.

2. Herr K., a machinist, aged twenty-six, also strong and healthy, was attacked on April 16, with profuse diarrhoea, which had been preceded by colic. The attacks could not be referred either to a chill or to any error in diet. When he had taken the carbolic drops for some days without relief, he expressed his surprise that the attacks should always begin at a fixed time toward mid-day, and then occur twice in the night, whilst from midnight and during all the forenoon he was quite free from his troubles. A few doses of quinine did their duty within twenty-four hours.

Most of Dr. Rothe's cases of this kind were in adults, but there were some also amongst children, in which quinine had the like success. He has no exact notes of these, but thinks the number must have been some fifteen to twenty. Whether this intermittent diarrhoea may be due to some powerful affection of the sympathetic nerves, perhaps even of the solar plexus, and the vaso-motor nerves, he does not pretend to say, any more than he can determine what sort of irritation of a specific kind could occasion such a neurosis. The fact that one of the cases above described occurred in the highest part of a hilly city, and that the other happened in one of its lowest-lying parts, near the railway, whilst there were no attacks of intermittent fever at the time, appeared to exclude malarious influences. The periodicity, and the uselessness of ordinary remedies, were the only distinguishing characters of the affection.

[No remark is made as to temperature in these cases. It was possibly normal in the intervals.—*Rep.*]

WOLF ON A CASE OF ACUTE YELLOW ATROPHY OF THE LIVER.—Dr. Wolf, assistant-surgeon at Carlsruhe, writes an article to Betz's *Memorabilien*, Jahrgang xxi., Heft 3, of which the following is an abstract. He first discusses the pathology of the affection, giving the views of Frerichs, Rokitsansky, Traube, Hensch, Von Dusch, and others, noting the remarkable fact that out of thirty-one cases twenty-two were in females, and half of these were pregnant. The disease is, however, still rare enough to justify the publication of the following instance, from the Garrison Hospital of Carlsruhe in 1873, especially as there were some peculiar features in the case.

K. St., aged twenty-two years, had very early suffered from repeated attacks of dyspepsia. On October 10, 1873, he felt ill, after eating sausages. His symptoms increased till the 22nd, when he vomited after a meal of the same kind. Ever since

he had suffered from general malaise, fatigue, loss of appetite, bad taste in the mouth, and pressure and fullness in the stomach; and was admitted into the hospital on the 24th for these, and more especially for commencing jaundice. He was fairly nourished but of weak constitution. There were a yellowish-grey tinge of the skin and conjunctivæ, etc.; large white-coated tongue; pressure on the stomach was painful, not so over the liver; the size of the latter appeared to be normal. Liver dulness began in the right axillary line with the upper edge of the sixth rib, in the mammillary line with the fifth rib, and extended downwards four or five inches. The bowels were confined. He was ordered infusion of rhubarb with bitartrate of potash. On October 29 the jaundice was rather deeper. The urine showed bile-pigment; the tongue was still coated; the appetite was better; the bowels were now regular; the patient felt better, and sat up yesterday. Pulse slow and full. No fever. Evening temperature $36\cdot4^{\circ}$ Cent. ($97\cdot52^{\circ}$ Fahr.). The patient continued to improve steadily, when a fellow-patient died somewhat suddenly in the same room at 11 P.M. of acute oedema of the lungs. The necessary treatment greatly excited this jaundiced patient. On November 1, although the urine of the day before contained bile-pigment, without albumen, it was as clear as crystal, and had no trace of bile-pigment, but, on heating the urine with nitrate of silver and excess of ammonia, the silver was reduced. It also reduced copper in the presence of an alkali. A drop was dried on a slide to a syrupy mass, but no crystals could be detected in it. At noon he vomited, without knowing why. On November 2 the jaundice was deeper; there was no itching of the skin. The stools were solid and white. He seemed rather dull, and asked for a night nurse; then said he was quite well, and did not want a nurse; then complained of weariness, and soon fell into a comatose state. When awakened from this, he gave rational answers. Pulse regular, but a little quicker than before (72). Temperature as before ($36\cdot4^{\circ}$ Cent. In the afternoon he had a loose stool. The urine was still quite like water. On November 3 in the morning the patient was rather duller, and only answered when shaken and shouted to. The pulse had risen to 96. The tongue had a smutty appearance. The urine was perfectly clear, and free from pigment; it left no precipitate on evaporation. The left lobe of the liver scarcely reached the middle line. The upper limits of the right lobe began at the sixth rib, the lower border no longer reached the edge of the lower ribs. Percussion seemed to give him pain. The spleen was not enlarged. The skin was dry, the pupils were large, and reacted very sluggishly. On account of the persistent coma a warm bath and cold shower-bath were combined, but had no special effect, except that the skin was a little moister. Attempts at vomiting supervened, without actual vomiting. In the afternoon, his urine came away from him, staining his bed and shirt an intense yellow colour. Breathing was deep and regular (sixteen per minute), temperature $37\cdot6^{\circ}$ Cent. ($=99\cdot68^{\circ}$ Fahr.). Towards evening, about every hour and a half, he breathed more deeply and quickly, and gnashed the teeth, and had spasmodic movements of the arms towards the chest, especially when the region of the liver or that of the bladder was pressed upon. The belly was retracted. At 6 P.M. a peculiar unpleasant sweetish cadaverous smell was noticed in his breath,

and soon filled the room. Temperature $36^{\circ}8'$ Cent. ($=100^{\circ}4'$ Fahr.) On November 4 he passed the night in a state of deep coma. The respirations were deep and regular, though sometimes interrupted by quicker and shallower ones, generally accompanied by trismus and convulsions. Pulse small and frequent (118), but regular. The urine was passed unconsciously, strongly tinged with bile. The stomach being rather firmly pressed, he vomited a small quantity of a brownish red fluid. Temperature $38^{\circ}2'$ Cent. ($100^{\circ}76'$ Fahr.) The liver dulness had become still smaller, and between the right mammillary and axillary lines, it was scarcely of the width of a hand. The pulse and respirations were as before. There was the same peculiar smell. Slight œdema supervened. The convulsions became more marked and general. Towards 5 P.M. he vomited twice, but only a little epithelium from the mouth was found in the vomit. His blood contained numerous white corpuscles. Pupils widely dilated, and did not respond to light. Temperature $38^{\circ}6'$ Cent. ($=101^{\circ}$ Fahr.) At ten minutes past 5 P.M. he died.

At the *post mortem* examination, besides the signs observed in life, there was considerable venous hyperæmia of the dura mater, which was rather adherent with numerous Pacchionian glands. The longitudinal sinus was full of dark red blood. The veins of the pia mater were gorged with blood. There was some serum between the convolutions, and about two tablespoonfuls of blood-stained serum in the posterior fossa of the skull. Numerous puncta cruenta were seen on slicing the brain. There was some fluid in the left pleural cavity. Pleural adhesions were found on the right side. Some fluid was contained in the pericardium. The heart was flabby, the valves healthy, but the papillary muscles had undergone some fatty degeneration. The posterior part of both lungs was filled with dark blood (hypostatic congestion). The bronchi were full of frothy fluid. The stomach contained a little black smeary fluid; its mucous membrane was somewhat strongly corrugated in the greater curvature, and showed numerous old extravasations in the fundus, and recent ones at the pylorus. The spleen was not enlarged; its capsule wrinkled. There was considerable venous hyperæmia of the kidneys; commencing granular parenchymatous degeneration. There was also a yellowish coloration of the pyramids. The liver was not at all adherent, but was diminished in all its diameters. The left lobe measured from before backwards only 11 centimètres ($4\frac{3}{8}$ inches), the right lobe measured in the same direction 16 centimètres ($6\frac{1}{2}$ inches); in breadth the left lobe was 8, and the right 12.5 centimètres ($3\frac{1}{4}$, and a little under 5 inches). The thickness of the left lobe was only 2 centimètres ($\frac{3}{4}$ of an inch), that of the right 4 centimètres ($1\frac{5}{8}$ inches). The whole weight of the liver was only 630 grammes (less than 20 ounces). Its capsule was wrinkled. The posterior part (by hypostasis) was of a dark brownish red, but showed numerous little projecting 'islands' of a lighter yellow colour varying in size from a pin's head to the size of a small apple. Similar spots appeared on the upper surface of both lobes, especially on the left, like Spigelian lobes. On section, similar bright yellow spots appeared, like small knobs. Perfect acini were not easily recognised in the almost everywhere soft and sodden tissue, but where present, the liver-cells appeared somewhat enlarged, often with double nuclei, and they had also undergone some fatty degeneration. In general

the microscope showed little but formless detritus, numerous granules, drops of oil, heaps of acicular crystals of tyrosine, and globules of leucine, along with fibres of unaltered stroma. The bile-ducts and gall-bladder were pervious, but empty.

The effects of terror on this patient's urine and on his disease were very remarkable. One symptom common in acute yellow atrophy, viz. enlargement of the spleen, was absent. Frerichs, however, met with four out of twenty-three cases of this disease, in which the spleen was normal in three, and small in the fourth.

ZIMMER ON LEVULOSE IN THE URINE IN DIABETES.—In the *Deutsche Medicinische Wochenschrift*, for July 13, 1876, Dr. Zimmer, of Carlsbad, writes on the occurrence of levulose (left-handed glucose) in the urine of a diabetic patient. The patient, Dr. V., aged twenty-nine, was a Dutch military surgeon, of the Jewish faith. His father died at sixty, after suffering from jaundice about a year. The mother seems to have died young, of phthisis. The paternal grandfather seems to have had diabetes during his last (sixty-ninth) year of life. Dr. V. had several attacks of jaundice in 1864 and 1865. He had also been troubled with boils and muscular rheumatism, and in 1873 and 1875 had attacks of intestinal catarrh. The last was very severe for one week, and only yielded to large doses of opium. From this time he had not only great thirst, but polyuria also, and he became so weak as to be forced to give up his hospital duties. Since the middle of July last his complaint had undoubtedly been diabetes mellitus, and he lived on an almost exclusively meat (flesh) diet. Under this regimen the urine had a specific gravity of 1026 to 1030, and contained about 2 or 3 per cent. of sugar. On reaching Carlsbad, on August 28, 1875, he only weighed eight stone, clothes and all (fifty-one kilos). There were then large appetite, great thirst, extreme weakness, slight splenic enlargement, but nothing abnormal was detected in heart, lungs, or liver. There was no smell of acetone in the breath. Taste was normal. A highly nutritious special diet was ordered him, and it is believed that he strictly adhered to this. The sugar slowly but gradually diminished. August 29: Twenty-four hours' urine was 4 litres (about 140 ounces). It was rather strongly yellow, had a strong acid reaction, was free from albumen, and clear when first passed. After long standing, some uric acid crystals and epithelium were deposited. The urine in the day-time had a specific gravity of 1055, and, when tested with Fehling's solution, showed 9.8 per cent. of sugar. On decolourising it with plumbic acetate, and placing it in the polarising apparatus, Dr. Zimmer found, to his astonishment, left-handed polarisation, not doubtfully, but indicating 2.2 per cent. of left-handed sugar, or levulose. [The observed, not the calculated, percentages are given.] As this left-handed polarisation was indubitable, and yet did not agree with the high specific gravity, or the results of the copper test, it was resolved to repeat the observation on other days. September 2: Twenty-four hours' urine = 140 ounces. Specific gravity of day urine, 1042. Sugar by copper process, 5.3 per cent. The polariser showed levulose. The night urine had a specific gravity of 1018. Sugar not estimated. September 8: Twenty-four hours' urine = $2\frac{1}{2}$ litres (88 ounces). Specific gravity of day urine, 1020; sugar 1.56 per cent. Levulose, by polarisation, 0.5 per cent. Specific gravity of night

urine, 1013; only a faint trace of sugar by copper test. Result of polarisation also null. September 17: Urine = $1\frac{1}{2}$ litre ($46\frac{3}{4}$ ounces). Specific gravity of day urine 1019; levulose by polarisation 0.3 per cent. It was difficult to estimate the sugar by copper. A smutty yellow colour was produced on heating with copper, and the precise limits of colouration were not easily defined. Specific gravity of night urine = 1015. Sugar not estimated. On the 18th he suddenly left Carlsbad, on account of an uncle's death. The result of the twenty-one days' dieting and drinking of the 'Mühlbrunn' water was so far favourable. He had gained nearly four pounds' weight, and the sugar was reduced to traces. By letter dated February last, the improvement is said to have continued up to date. Dr. Zimmer calls attention to the following facts. 1. This urine reduced the copper test very quickly and freely. It never displayed right-handed polarisation. The urine always showed left-handed polarisation. These combined properties of reduction and left-handedness distinguish levulose, or fruit-sugar. 2. So far as Dr. Zimmer knows, levulose has only been found in urine by Gorup-Besanez, and once (for a short time only) by Seegen. The reason may be either that it is really rare, or that it is overlooked, since it can only be distinguished from grape-sugar by its optical properties, for it reduces copper, forms alcohol and carbonic acid by fermentation, etc. Even in the polarising apparatus, if only small quantities be present along with a quantity of grape-sugar, it may easily be overlooked. 3. Külz found, both in mild and severe cases of diabetes, that the excretion of sugar was not increased by either grape-sugar or inulin. Both these substances must therefore have been assimilated. Although this kind of sugar may be easily assimilated, we must not hastily assume that it is harmless in diabetes, since, as Dr. Zimmer remarks, his patient was only taking a very moderate quantity of almond biscuits (*Mandelzwickbäck*), and soup or broth containing roots of different kinds, and yet for three weeks continued to excrete levulose. Moleschott, indeed, says that almonds only contain cane-sugar. However, Külz's observations and those of Dr. Zimmer render it probable that this is decomposed in the body into levulose and grape-sugar. 4. This patient's urine contained grape-sugar as well as levulose. As on August 29th, 9.8 per cent. of sugar was indicated, had this been all levulose the polarisation would have indicated twice as much, or 19.6 per cent., for it is well known that the angle of deviation to the left in the levulose is twice as large as that to the right from grape-sugar. But since, on August 29, only 2.2 per cent. was indicated, it is clear that another kind of sugar must have been present. Had these been present in equal quantity, the negative or left-handed polarisation would have been 4.9 instead of 2.2 per cent.

Dr. Zimmer discusses the relations of glycogen to different kinds of food. We need not follow this discussion. He thinks his own experience confirms that of Külz. He therefore recognises three forms of diabetes: (a) a slight form, in which sugar is excreted only on mixed diet; (b) a severe form, in which, when all vegetable diet is withdrawn, sugar is found in the urine, being formed at the expense of albuminates; (c) a mixed form, in which sugar sometimes occurs when carbohydrates are taken, whilst at other times it is found even after long use of an animal (flesh-meat) diet. Dr. Pavy has noted such cases, for he reports one in which a few ounces

of bread caused sugar to appear in the urine, and this lasted some days, more sugar being excreted than was ingested. These forms do not tend to pass one into the other, according to Dr. Zimmer's experience (now extending over several years). He has never seen the slight form pass into the more severe one. The mixed cases once now and then become more severe. He thinks this an argument against the view that diabetes mellitus is simply a disturbance of the glycogenic functions of the liver.

W. BATHURST WOODMAN.

EXTREME SLOWNESS OF PULSE.—M. Tillaux has recently had among his cases at the Lariboisière hospital, some instances of extreme slowness of pulse. The following account of one of them is taken from the *Gazette des Hôpitaux*, August 12, 1876. The patient was a man aged seventy-six, a rag-picker ('chiffonnier'), who had come into the hospital to be treated for a hydrocele of the left side. The most remarkable thing about him, however, was the extreme slowness of his pulse, twenty-one pulsations a minute on an average. Last year he was in the hospital for a hydrocele of the other side, but at that time nothing abnormal drew attention to his circulatory apparatus. The man complained only of his hydrocele, and was of a jovial disposition. The pulse was regular, and the cardiac revolution appeared to be almost as rapid as in the normal state; the two sounds and the short interval which separated them scarcely occupied half a second; it was the long interval which was so extraordinarily prolonged, lasting almost two and a-half seconds. This long interval was complete in all senses of the word; absolutely nothing could be heard in the heart. With the first sound, on the contrary, commenced a distinct murmur, which continued during the short interval, and terminated abruptly with the valvular click which constituted the second sound. It was divided, so to speak, into two parts; for, at first very clear, it diminishes, and then gained in force until the moment when it finished. Its maximum was towards the apex of the heart; it was there that it was loudest; it might be heard, also, towards the base, but more dull; it might equally be found prolonged towards the axilla, even outside the left nipple. The heart appeared large; the apex beat further out and lower down than normal. There was some emphysema of the lungs, and some times sonorous rhonchi momentarily interfered with auscultation of the heart. The pulse was taken four days running; on Monday it was 21, on Tuesday the same, on Wednesday 22, on Thursday 21. Generally it was perfectly regular; the intervals were equal, and the cardiac revolutions maintained the same duration. The patient, after a few days, showed signs of œdema of the legs and trunk.

W. DOUGLAS HEMMING.

SACHS ON THE HEPATITIS OF HOT CLIMATES.—In an article in the *Archiv für Klinische Chirurgie*, Band xix. 1876, Sachs says that the predisposition of the inhabitants of tropical countries to suffer from affections of the liver depends on diminution of the respiratory function, and compensating development of the functions of the liver. Amongst the efficient causes, the foremost is the use of alcoholic drinks. Hepatitis is not, as is generally believed, consecutive to dysentery, but dysentery often depends on hepatitis. The invariable sympathetic pain in the right cervical, clavicular, and scapular regions, he attributes to irritation of the terminal fibres of the

phrenic nerve, which sends branches to the liver by the suspensory ligament. The tongue is white, moist, and thickly coated; there are loss of appetite, nausea, and rarely vomiting. Insomnia is a well-marked symptom. The temperature is not high; when it goes beyond $39^{\circ}5$ Cent. ($103^{\circ}1^{\circ}$ Fabr.), a complication is indicated, such as thoracic affections, which often cause death.

BOCHEFONTAINE ON PRODUCTION OF EPILEPTIC ATTACKS IN MAN BY TICKLING THE SKIN OF THE NECK.—In the *Archives de Physiologie*, 1875, Bochefontaine records the case of a man affected for several years with epileptic dementia, who had paroxysmal attacks separated from each other by short intervals over a period of several days, the mental capacity being completely effaced whilst the crises lasted. Besides the true paroxysms, the patient suffered from attacks of partial epilepsy, which were much less violent. He was warned of the latter attacks, and had time to sit down.

This man had an epileptogenic zone analogous to that of guinea-pigs, in which the sciatic nerve has been cut. The patient being seated, the experiment was made during one of the calmest intervals between two attacks, M. Bochefontaine tickling the lobule of the left ear, and the corresponding cervical region with a feather. The patient was immediately seized with one of the lesser paroxysms. The experiment was several times repeated, and always with the same results.

DISEASES OF CHILDREN.

KERSCH ON PERITONITIS IN CHILDREN.—Dr. Kersch, of Prague, in commenting (Betz's *Memo-rabilien*, vol. xxi. Heft 2) upon the difficulty of determining the presence of peritonitis in children, concludes that the character of the breathing furnishes an almost pathognomonic symptom. Every deep inspiration produces pain in the hypochondria, and the breathing is therefore shallow and frequent, and is of the thoracic type. There is no impediment to expiration, and consequently the child can still cry vigorously. The characteristic breathing, then, consists of a long expiration followed by a series of extremely short inspirations, and, as a rule, each

expiration is accompanied by a cry of the same duration. If this symptom be associated with a drawing up of the limbs, the diagnosis may be considered certain. The prognosis is more favourable than in adults, at least as regards life; but when it occurs in girls between the ages of five and eight, the author believes that it is an important factor in the production of subsequent sterility; indeed, all the cases that he has known have had this result. Ten cases which were attacked between the ages of five and fourteen years, have been watched by the author. All have now been married some years, and all are childless. In the treatment of peritonitis in childhood, if the ordinary measures fail to reduce the quantity of fluid, Dr. Kersch employs puncture; if the fluid do not escape readily, he keeps the wound open for some days, or, should this heal prematurely, he makes a second puncture through the scar of the first one.

Two cases are appended. One of these, a girl, aged five and-a-half years, had been much neglected, and when seen was in a condition bordering on collapse. The ordinary means were tried for a short time, but without effect. Puncture was then resorted to, and was performed in all three times. At the end of two months the child was quite strong and healthy. The other patient, a girl, at fourteen, recovered without puncture. She was treated with large doses of quinine, morphia in weak solution, and cold compresses to the abdomen. She is now twenty-four years old, and has been married six years, but has no children. The author believes the barrenness to be due to the contraction of a layer of lymph which has been deposited upon the ovaries, and the consequent interference with the nutrition of these organs.

UNTERBERGER ON RELAPSING FEVER IN CHILDHOOD.—In an interesting paper in the *Jahrbuch für Kinderheilkunde*, Band x. Heft 1 and 2, Dr. Unterberger, of St. Petersburg, details his experience of forty cases of relapsing fever in children. The blood of every patient was microscopically examined, and, during the pyrexial stage, spirillæ were constantly present. Their number varied very much, even within a few hours. Their movements were most lively towards the end of the febrile stage; in the apyrexial stage, with one exception, they were never visible. The spirilla is described as an extremely thin, spirally twisted fibre of the length of from two to three or more blood-corpuscles, and of the thickness of a corpuscle seen in profile. The author has looked for them in vain in many other infectious diseases, and attaches, therefore, such importance to their presence, that he affirms that there can be no relapsing fever without spirillæ, and no spirillæ without relapsing fever. The other changes in the blood were that the colourless corpuscles were increased in number, and that epithelioid cells, often in a state of fatty degeneration, were present. The remarks on etiology are confirmatory of what is already believed. No patient had less than two paroxysms; a third occurred in nineteen out of the forty; a fourth, in one only. In seventeen of the cases, the crisis was preceded by a pseudo-crisis, which lasted from eight to thirty-six hours, and was characterised by a reduction of temperature with either sweating or diarrhœa. The true crisis occurred from twelve to twenty-four hours later; the temperature meanwhile having risen. The average duration of the first febrile attack was

6 days; of the first remission, 6·7 days; of the second attack, 5 days; of the second remission, 7·3 days; and of the third attack, 3·5 days. The highest temperature recorded was 108·6° Fahr. The body-weight, owing to the excellent appetite of the patients, was very slightly affected. The pulse-rate did not fall suddenly at the crisis, but was some days before it reached the normal standard. This is important in the differential diagnosis between this disease and typhus. Of the complications, those affecting the respiratory system were rare and trivial. With the circulatory system it was otherwise; for organic disease of the heart supervened in five cases. Anæmic murmurs were noticed in seventeen. The condition of the tongue the author considers very characteristic; it was broad, pale, moist, and slightly coated. Vogel's red triangle was never seen. Parotitis was present in two cases; iritis, with opacity of the vitreous body, also in two. Other complications occurred only in single cases. There was no hebetude, even when the temperature was at its highest. The liver, especially its left lobe, was always enlarged and tender, and icterus was observed in five cases. The enlargement of the spleen, which was constant, was very rapid, and preceded that of the liver. Pain in these organs was elicited by palpation; and, when the increase in size was very great, by the least movement of the body. With the remission, the hyperæsthesia ceased, and the spleen became softer and smaller. The urine presented nothing characteristic; albumen was never detected. The skin was pale at first, waxy or ashy afterwards. A macular erythema was present in two cases; herpes labialis in three; œdema, affecting chiefly the scrotum, in two. An alteration in the nails was not looked for, except in the last few patients admitted. The characteristic sign, Dr. Unterberger believes, consists in dull transverse stripes, in number corresponding to that of the paroxysms.

In the treatment, besides the usual indications, the importance of reducing the size of the spleen is insisted on. For this purpose, electricity was employed, and, under its influence, the organ speedily diminished in size. In one case, this diminution was accompanied by a corresponding increase in the size of the liver, as already observed by Botkin. From the difficulty of applying electricity in private practice, and from the resistance offered to it by children, it was afterwards abandoned in favour of ice-bags with equally good results. To reduce the temperature, salicylate of soda was employed, and was found preferable both to the free acid and to the ammonium salt. But, although the temperature was lowered, the appetite was so much impaired that cold baths were substituted for it. No drug appeared to exercise any influence on the vitality of the spirillæ. One patient died; and, at the necropsy, the spleen showed five infarcts of the size of a hazel-nut, and one of the size of a hen's egg; the liver was fatty; the peritoneum contained nearly two pints of greenish flocculent exudation. The endocardium was much injected, and the posterior segment of the mitral valve was retracted, and was fringed with reddish growths as large as peas.

LÖCHERER ON A CASE OF CONGENITAL ICTHYOSIS.—The subject of this paper (*Aerztliches Intelligenzblatt*, July 11, 1876) was born at full time, of a perfectly healthy mother, who had previously had three children. No skin-disease existed in any member of the family. The child, when born, was

entirely covered by a leathery armour, which, in many places, showed fissures and bleeding depressions. These last rapidly increased in size and number. The layer felt like hard leather, and was from one-eighth to three-sixteenths of an inch in thickness. Its colour was at first white, afterwards a dirty yellow. The rigidity of the layer had retarded the development of the fingers and toes, as well as that of the nose, lips, ears and eyelids. The nose projected very slightly beyond the face, and seemed, at first sight to consist only of nostrils. The mouth was always wide open, and the upper lip did not cover the jaw. In the place of eyes, two red swellings were all that could be seen—these were the everted eyelids. There were no fissures on the hands and feet, which indeed were puffed in such a way as to resemble spina ventosa. The fingers and toes were rudimentary; though nails and phalanges were all present in miniature. The child lived two days.

RALPH W. LEFTWICH, M.D.

MABBOUX ON FISSURE OF THE ANUS IN AN INFANT.—A case of this kind, occurring in a girl aged two months, is described in the *Gazette des Hôpitaux* for August 5. It derives its interest from the extreme rarity of the affection in childhood. The symptoms which pointed to the affection resembled those observed in adults—great pain on defecation, constipation, spots of blood on the motions, etc. The fissure was found on the right side, between two folds of mucous membrane. It yielded in six days to treatment with rhatany ointment.

SURGERY.

RIEDINGER ON INFLAMMATORY SEPARATION OF EPIPHYSES.—Dr. Riedinger, of Würzburg, reports in the *Verhandlungen der Physikal-Medicinische Gesellschaft zu Würzburg*, Bd. x. Hft. i., an interesting case of inflammatory separation and necrosis of the superior epiphysis of the left femur. The author, in some preliminary remarks, states that osteomyelitis, osteochondritis, and cognate processes, attacking young subjects, may have varying results according to the constitution of the patient, the character of the morbid process, and the portion of the bone affected. In subjects who have not reached the period of puberty, the inflammatory process may result in the separation from the shaft of the inflamed bone of one or two epiphyses. In some instances reunion takes place, but usually with more or less irregularity and distortion, and with contraction of the corresponding articulation. In other cases, the reunion of the epiphysis and diaphysis is imperfect, and a kind of false joint is formed. Again, reunion may fail altogether; and then the detached epiphysis, cut off from its nutrient supply, may undergo necrosis, and act as a foreign body. Cases have been recorded, in which the loose epiphysis had contracted adhesion to the shaft through secondary inflammatory action. According to Bardeleben, a necrosed epiphysis may melt down with profuse suppuration, and be entirely eliminated by the discharge in minute fragments through fistulæ. The subject of Dr. Riedinger's report was a badly developed and very anæmic youth, aged seventeen years, who in the summer of 1872 had been suddenly attacked with acute pain in the region of the left hip, and soon afterwards with intense fever and rigors, swell-

ing and redness over the seat of pain, and œdema of the corresponding leg and foot. Seven weeks later an incision made at the upper part of the left thigh had given exit to a quantity of pus. In consequence of the persistence of the suppuration and the consequent debility of the patient, it had been decided to place the case in the Würzburg Hospital, under the care of Professor von Linhart. The left lower extremity had been shortened by about three inches, and rotated inwards. The patient lay constantly on his right side, and there was marked lordosis of the lumbar vertebræ. About the hip were several fistulæ leading down to the joint. The trochanter major was much elevated, and very prominent. The whole of the limb was much emaciated. On probing the seat of disease, carious bone could be made out. The patient could not be made to move the diseased limb on account of pain, and passive movements made after the administration of chloroform were much restricted. The case was diagnosed as one of suppurative coxitis with luxation, although there was some doubt as to the position of the head, which could not be felt. The operation for excision of the hip was performed. The ordinary incision was not made, but a fistulous canal near the antero-superior iliac spine was connected by a stroke of the knife with another canal over the trochanter major. The joint could then be readily reached. A hard, rough, and movable body placed near the acetabulum, having been removed by forceps and examined, was found to be the head of the femur in a state of necrosis, and quite detached just at the seat of the insertion of the neck of the bone and at a part precisely corresponding to the epiphysal line. This necrosed head had remained in the acetabulum, whilst the neck and diaphysis of the bone had been displaced upwards and backwards. As the remaining portions of the joint were found in a healthy condition, no further operative proceedings were taken after removal of the portion of dead bone. The surface of the acetabulum was found covered by a layer of healthy granulation-tissue. The death of the detached epiphysis, in this case, Dr. Riedinger remarks, is not surprising as the ligamentum teres had been destroyed, and all supply of nutrition cut off. Allusion is made to the remarkable difference in the results of inflammatory loosening of the upper femoral epiphysis and of intracapsular fracture of the neck of the bone. In the latter lesion, though the line of fracture may correspond very closely to the former epiphysal line, though the detached head may never again become united with the rest of the bone, and though the age and condition of the patient are very often unfavourable to the preservation of vitality in the small fragment, yet this fragment very rarely undergoes necrosis. This difference in results is attributed to the presence in the former case of the element of active inflammation. The author, in concluding, expresses his doubts whether luxation of the head of the femur is so frequently met with in connection with coxitis as is generally supposed; and he seems inclined to believe that, in many of the cases of supposed complete luxation, the real condition consists in displacement of the neck and shaft from the detached head, which lies either loosely, or fixed by more or less ankylosis, in its acetabulum.

W. JOHNSON SMITH.

DUNNING ON THE DIAGNOSIS OF ANEURISM.—Dr. W. B. Dunning relates the two following cases in the *New York Medical Record* for July, in

illustration of a remark of Dr. Stephen Smith, 'that the symptoms most relied on in the diagnosis of aneurism may be present when there is no aneurism, and may be absent when aneurism exists.'

1. *Aneurism mistaken for Semi-Malignant Tumour.*—A few years ago Dr. Dunning was invited, being then house-surgeon to Bellevue Hospital, to see a case of tumour in the popliteal space, which it was proposed to remove. The patient was an Irish labourer, thirty-two or thirty-three years of age, who had always had good health until two or three years before, when he first noticed a small growth of the size of a walnut in his left popliteal space. He had never received any injury in this region, had never had syphilis, and knew of no cause which could explain its presence. In consequence of its increasing size and its apparent effect on his health and spirits, the patient had been for some months desirous of an operation for its removal. His surgeon, a man of skill and experience, had repeatedly examined the tumour, and, without expressing a positive opinion, save that it was not an aneurism, was inclined to regard it as a sarcoma. When Dr. Dunning saw the patient he was somewhat emaciated, but on the whole all his functions were in a healthy condition. The tumour was then about nine inches in circumference, completely filling the popliteal space, and protruding from it about three inches, spherical, hard, and inelastic, non-adherent to the skin, having no pulsation, uninfluenced in size by pressure on the femoral artery, and having no bruit. It was a tumour in the course of an artery, but presented no other feature whatever of an aneurism. As an *experimentum crucis*, a hypodermic needle was inserted, but its withdrawal was followed by no liquid of any kind. The attempt to operate was attended with the most profuse hæmorrhage, followed in a few hours by death. The tumour was found filled with concentric layers of fibrine occupying its entire space, save a small cavity in the course of the artery. It had no appreciable pulsation nor bruit, because so considerable a mass of fibrine intervened between the artery and the examining finger. It did not diminish in size on pressure of the artery above, because its constituents were almost wholly solid, and this pressure could remove only the liquid portion; and finally, an exploratory puncture brought no blood, because the needle penetrated only into the solid fibrine.

2. *Fatty Tumour mistaken for Aneurism.*—A lady, over eighty years old, who recently died, had had an immense tumour on the right side of the neck, which had been regarded by all who had examined her as an aneurism. It had existed over thirty years, and her friends had been repeatedly warned that it might rupture at any time and the patient bleed to death. At the time of death, this tumour was about thirteen inches in circumference, of an ovoid form, non-adherent to the skin, inelastic, hard to the touch, save at one circular spot an inch in diameter, and had presented three features of an aneurism, viz.: (1) a tumour in the course of an artery; (2) an expansive pulsation felt distinctly by the finger placed on any part of the tumour; and (3) a distinct bruit. The *post mortem* section showed an immense fatty tumour, surrounded by layers of calcareous plates.

EXCEPTIONAL SITUATION OF A POPLITEAL ANEURISM.—In the notes of practice at Bellevue Hospital, in the *New York Medical Record* for

July 29, a case is recorded in which the patient, a labouring man, aged forty-two, had an aneurism of the popliteal artery which, at the time of the operation, four months after the occurrence of the accident which caused it, had increased the circumference of the limb two and a half inches, and the entire limb below its situation was somewhat swollen. The situation of the tumour was quite exceptional, for it was found to overlap only a small part of the outer and lower border of the popliteal space; the chief extent being to the outer aspect of the leg and below the popliteal space. The question arose, was not the tumour a pulsating tumour of the bone? It was believed to be an aneurism, because it was a pulsating tumour—a tumour with thin walls, a tumour that could be reduced in size by pressure upon the tumour itself, and also upon the artery above it, and was a tumour over which a distinct murmur could be heard, synchronous with the first sound of the heart. For its cure the femoral artery was tied, and the patient did well.

PITRES ON THE MODE OF FORMATION AND THE STRUCTURE OF THE CLOTS WHICH DETERMINE HÆMOSTASIS.—M. A. Pitres (*Archives de Physiologie*, May and June, 1876) gives the result of his direct observations of the mechanism of hæmostasis in frogs and young warm-blooded animals. He quotes first the generally received opinion that the clots are formed by the coagulation of blood in the same manner as this takes place in a bleeding cup; he then refers to a paper by J. F. D. Jones ('A Treatise on the Process employed by Nature in Suppressing Hæmorrhage from Divided and Punctured Arteries, and on the Use of the Ligature,' London, 1806) to show that long ago direct observation had proved that this process is not so simple, but that, according to Jones, the thrombus is composed of three layers—one external, red, and resembling ordinary blood-clot; a second, lying in the wound itself, white, and called by Jones the lymphatic clot; and, third, a red internal clot. More recently, M. Zahn (*Virchow's Archiv*, 1874), directly observing by the microscope the process of hæmostasis in the mesentery of the frog, saw that the lymphatic clot of Jones is really formed by the aggregation of leucocytes. M. Pitres, following Zahn, completely confirms his statements, and proves, by washing away the blood as it flows, so as to prevent the formation of external clot, that the essential element in the hæmostatic process is this lymphatic clot, the function of the external clot being only secondary and accessory to the other. The internal clot plays no part in hæmostasis proper; it occurs secondarily, and only when the circulation has been totally interrupted in a vascular *cul-de-sac*, and is the consequence of complex changes in the plasma, the corpuscles, and the walls of the vessel, and not the result of coagulation of the blood by a mechanism analogous to that which outside the body brings about the formation of clot by the solidification of the fibrine.

ROBERT SAUNDEY, M.B.

CRAWFORD ON TRANSVERSE FRACTURE OF THE PATELLA FROM DIRECT VIOLENCE.—Dr. J. H. Crawford, of Wiscasset, Maine, writes (*New York Medical Record*): 'Noticing a case of direct fracture of the patella chronicled in reports of practice of Bellevue Hospital, I would wish to state that I have had a somewhat similar one. Miss J.,

of Metuchen, New Jersey, while stepping from a platform to the railway track, slipped and fell, striking her right knee against the rail. She was conducted home, and when I saw her, the same day, I found transverse fracture of the patella, with considerable displacement. I used a stimulating lotion, and the following day drew the fragments of bone together, retaining them with strips of adhesive plaster, enclosing the whole leg at an oblique angle, and retaining it in this position for six weeks, at the expiration of which time I commenced free motion of joint with satisfactory results. At the expiration of nine weeks the patient, for the first time since the fracture, stood on her leg, and finally had a comparatively perfect union, with free use of the joint as before the fracture.

[Might not the patella have been broken during the fall, and not by the blow against the rail?]

ALLIS ON THE TREATMENT OF FRACTURE NEAR THE ELBOW-JOINT.—Dr. O. H. Allis, in an article in the *Philadelphia Medical and Surgical Reporter* for July 1, disapproves of the use of rectangular splints in the treatment of fractures involving or approximating the elbow-joint. He points out that the humerus and ulna do not lie in the same plane; a line drawn along the inner border of the humerus falls about two inches below the end of the ulna, and the bones join at an angle of about 175°. Hence a straight or rectangular splint applied along the inner side of the arm, in fracture of the humerus just above the condyles, in fracture of either or both condyles, in fracture of the olecranon process, or in the upper third of the ulna, would produce deformity. The defect holds good in all the angular splints, whether anterior or posterior, provided the two arms of the splint lie in the same plane. To have a perfect wooden splint, one should take the angle of the sound limb as his guide in its manufacture. If it be made with a hinge, it can be applied with the arm extended, as in this position one can the more advantageously compare the two limbs. A few strips of adhesive plaster may be sufficient to secure it to the forearm and arm, and then bending the arm to the angle most desirable or convenient, the dressing may be completed and the forearm put in a sling. Such a dressing will not produce deformity, and will permit motion at the proper time, without removing the splint. In the use of the anterior angular splint the thumb should look forward, not upward. Dr. Allis does not know any splint that possesses the combined advantages of the felt splint in injuries of the elbow-joint. By first dipping the felt in hot water it can be made pliable, and thus be moulded and adapted to the natural contour of the limb. It soon hardens, and then becomes a support and protection to the part; a security against displacement. With the felt material it is not a matter of importance whether it be adapted to the anterior, posterior, or lateral aspects of the limb, since it is applied in a soft, yielding condition, and obviously incapable of displacing the parts; while the wooden splint, incapable of accommodating itself to the part, will, with the applied bandage, gradually draw the fractured part to it.

The angle at which nature has joined the bones of the arm is to the labouring man a matter of great practical importance. By taking advantage of this angle, which he instinctively does, he is enabled to rest the internal condyle of the humerus upon the brim of the pelvis, and thus carry a bucket of water

freely from his legs, and that, too, with the least expenditure of muscular force; while with this angle effaced the weight must either be removed from the body by great muscular effort of the deltoid, or offer an almost insuperable obstacle to locomotion.

In his own cases Dr. Allis never uses splints, but always extemporises a dressing. In fracture of the condyles in children, he usually employs adhesive plaster. He cuts the strips about two inches wide and eight or ten inches long, and placing the arm in an easy extended position, he incases the limb from a few inches below the shoulder to the wrist, taking care that each piece overlaps the preceding one. Over this layer of plaster he places another, and about the joint he sometimes adds a few pieces of binders' board, dipped in hot water.

Certain advantages may be ascribed to the dressing of adhesive plaster, especially in children.

1. It sticks to the limb without compressing it.
2. It allows the child to bend its arm slightly, if it desires to do so.
3. By each strip overlapping its fellow, it becomes a complete encasement, at once light, flexible and adherent.

Should a starch dressing be used (or the white of eggs and flour), both of which make an admirable dressing, the same precaution taken in using the adhesive plaster should be followed, viz., to apply it on strips of muslin about two inches wide and eight or ten long, and under no circumstances to employ a continuous bandage.

Having dressed the arm, he directs the parents, if the child have pain, to remove the dressing, or bring it immediately back to him. He always sees the child the second day, and often relieves a little pressure at the wrist, and after a few days, finding that the child does not complain of pain, he pays little more attention to it, until he removes it, in the fourth or fifth week; he has not found a single case where there has been excoriation. In seven cases of fracture of the condyle the arm has been kept extended, and no passive motion employed, during the entire cure, and in only two of the number was the dressing changed once, and this because it had become loose.

His objects in dressing the cases with the arm extended, and without passive motion, leaving them undisturbed during the entire cure, are:—1. To test the danger of ankylosis, which, he is persuaded, is greatly over-estimated; 2. Because in this position he would get the best possible results. In this respect, he says, he has secured all one could wish; he has seven cases of fracture of the condyle in which it would require careful examination to tell which arm had been injured.

MATERIA MEDICA AND THERAPEUTICS.

ROSENSTIRN ON THE LOCAL ACTION OF THE SO-CALLED ASTRINGENTS ON THE BLOOD-VESSELS. H. Rosenstirn (*Wüzburg. Phys. Med. Verhandlungen*, ix. p. 32, and *Centralblatt für die Medicin. Wissenschaften*, no. 35), tested solutions of nitrate of silver, acetate of lead, tannic, gallic, and pyrogallic acids, sesquichloride of iron, and alum, by placing them upon the mesentery of a curarised frog, and estimating the size of the lumen of the affected vessel by means of the microscope. Nitrate of silver acted most powerfully on the vessels; it was employed in solution from 1 to 10 per cent. The observation was often interfered with by the turbidity produced in the tissues. The contraction extended to about half the lumen of both arteries and veins, and in a much less degree in the capillaries. The reaction occurred within a few seconds. Stagnation generally took place in the vessels; permanent in the capillaries, and temporary in the arteries and veins. Tannic acid had exactly the opposite effect. Under its influence the arteries dilate, even the veins and capillaries to the extent of one-half of their lumen, and appear to be over-filled with blood-corpuscles. The dilated vessels become narrowed at once by the action of nitrate of silver. Gallic and pyrogallic acids have an action similar to tannic acid. Acetate of lead acts more feebly than nitrate of silver. It narrows the arteries and veins, but no effect was observed on the capillaries. Sometimes also standstill of the circulation occurs. A 10 per cent. solution of sesquichloride of iron had no effect; in a 50 per cent. solution it narrowed the vessels less than acetate of lead. This narrowing is limited to the arteries and veins, while the capillaries dilate. Coagulation and discoloration of the blood within the vessels often occur. The results of the alum solution were variable.

In order to exclude a reflex action, the spinal cord was destroyed and the heart ligatured.

The author therefore ascribes an astringent effect, i.e. contraction of the vessels, only to nitrate of silver and acetate of lead; whilst this action is doubtful for alum and solution of sesquichloride of iron, and is certainly not the case with the group to which tannic acid belongs.

ROSSBACH ON THE PHYSIOLOGICAL ACTION OF COLCHICIN.—J. Rossbach (*Pflüger's Archiv*, Band xii.), remarks that the most striking phenomenon produced by this drug is the complete loss of sensibility by paralysis of the peripheral and the central

nerve terminations. The reflex excitability is extinguished. The motor nerves and the muscles preserve their excitability till death. In many animals the paralysis is preceded by a stage of excitation, which in frogs may proceed to a spasmodic attack. The circulation of the blood is only slightly affected by the poison. The heart continues to beat even after the appearance of the paralysis of the central nervous system. The blood-pressure remains long unchanged, and sinks only at death, and the paralysis of the inhibitory cardiac nerves also occurs late. The respirations gradually become less frequent, until complete standstill occurs, so that one must conclude that the respiratory centre is paralysed. In warm-blooded animals, and especially in cats poisoned with this drug, the whole gastric and intestinal mucous membrane was swollen and strongly injected, and bloody mucus was found in the intestine. As a consequence of this, during life, there was diarrhoea, vomiting, and colic-like pain. The cause of the strong injection of the vessels was not determined. The fibres of the splanchnic and abdominal vagus were not paralysed. The kidneys were also strongly hyperæmic and their secretion diminished.

The action of colchicin occurs very slowly, and death only takes place after several hours. It is remarkable, as Schroff had already indicated, that the amount of the dose has no important influence either on the intensity or on the rapidity of the poisoning. A few centigrammes, in cats several milligrammes, suffice to produce death, which occurs through stoppage of the respiration, the heart still continuing to beat. In this stage tonic or clonic spasms sometimes occurred in rabbits and cats. These the author regards as the spasms of asphyxia. Doses smaller than are lethal have no effect.

The author, therefore, does not regard colchicin as a therapeutic agent of much value. It may be used as a local anæsthetic, and Gerhardt uses it as such, for application to the mucous membrane of the pharynx and larynx.

W. STIRLING, D.Sc., M.D.

OTT ON COCA AND ITS ALKALOID COCAIN.—Dr. Isaac Ott, of Pennsylvania, in the *New York Medical Record*, September 9, 1876, gives an account of an experiment made upon himself with coca, and the results of other researches with that substance and its alkaloid on man and lower animals. After chewing 60 grammes of coca leaves in the space of eight hours and forty-five minutes, Dr. Ott describes his condition as follows: 'Loquacity; eyes brilliant and moist; at length speech becomes thick; am in high spirits and full of hopes. In ten hours and fifteen minutes frontal headache again coming on; drowsiness; then retire, but unable to sleep. After a few hours deep sleep comes on, but is disturbed and not prolonged. Arise at 7.30 A.M.; face pale; eyes seem dry; lips bluish; take a light breakfast without coffee. Since 10.30 P.M. last night have had frontal pain; sensation in mouth still blunted. At dinner took three cups of coffee, which relieved me, but headache came on during the afternoon; taste blunted during the whole day.'

Dr. Ott finds that in man coca increases the pulse, elevates the temperature, dilates the pupil, and decreases the amount of water used and chloride of sodium excreted by the kidneys. Observations made with cocaine on the lower animals gave the following results. In small and large doses it causes

loss of co-ordination and decrease of motor power; it does not paralyse the anterior columns of the spinal cord. In small doses it increases the sensibility, which causes general convulsions upon irritation. Large doses abolish the functions of the posterior columns and sensory nerves. When gradually introduced into the system, it kills by stoppage of respiration. It reduces the pulse and arterial tension momentarily, and afterwards increases them. This effect is a result of an action on the heart and vaso-motor centre. It does not paralyse either the pneumo-gastrics or the vaso-motor centre, situated in the brain. It first excites and then paralyzes the centres of respiration. The pupil is dilated and the temperature, after a depression, rises. On striated muscles the course of contraction, as registered by Marey's comparative myograph, is similar to that with veratria. If coca and cocaine be compared with coffee and caffeine, in their physiological action, the result will be that they are very similar, and that coca and its alkaloid should be classed among the excitants, of which coffee is the chief example.

FRIGERIO ON THE TREATMENT OF EPILEPSY BY SUBCUTANEOUS INJECTION OF BROMIDE OF POTASSIUM.—In the May number of the *Archivio Italiano per le Malattie Nervose* (quoted in *Paris Médical*, August 31), Dr. Luigi Frigerio gives the results which he has obtained by this proceeding. At first he employed by preference a solution containing 2 centigrammes ($\frac{1}{3}$ grain) to the gramme; he has given as much as 60 centigrammes ($8\frac{1}{2}$ grains) at each injection, but this dose causes local trouble; he has even seen an injection of 25 centigrammes ($3\frac{1}{2}$ grains) cause abscesses and eschars. He chooses the skin of the fore-arm. He has remarked that by gently rubbing the point at which the puncture is made, the absorption of the injected matter is facilitated and the chances of abscess avoided. It is useful also to prescribe repose of the limb, and Dr. Frigerio also often puts the patient to bed. He has observed a rapid diminution in the number of attacks. The local effects are less frequent, and relatively slight.

MURRAY ON DAMIANA.—The *New York Medical Record* for August 19, 1876, contains an article by Dr. Alexander Murray, of New York, on the new remedy damiana, the therapeutic value of which he has tested in nervous diseases, and especially as an aphrodisiac; particulars of five cases are given, and the following are the concluding portions of the paper.

'I have noticed that, when damiana had been taken for a week or two, it invariably produced (in about two-thirds of my patients) an eruption of acne on the head and body. It also produced large soft evacuations from the bowels, especially in those of a constipated habit. The drug did not act as a laxative, but more as an alterative; in fact somewhat similar in its results to the extract of belladonna, when administered in chronic constipation. I did not observe any marked effect on the heart, liver, stomach or bladder. In a few instances I noticed the diminution of the phosphates, and almost the entire absence of the oxalate of lime, which usually appears in the urinary secretion in cases of nervous affections, and especially in cases of impotency.'

'The value of damiana in impotency is more apparent in stimulating venereal desire than in restoring the vigour or power of the virile member. In

several cases the drug failed to manifest any curative effect, while in others, particularly in those arising from an attack of paralysis (hemiplegia), even of six or eight years standing, it was more or less beneficial.

'Damiana is by no means an agreeable remedy to take. The bitter slightly acrid taste, and the "sagey" flavour are disliked by many patients. It sometimes excites nausea or vomiting, especially when taken on an empty stomach, or when the dose is not largely diluted with some menstruum.

'The fluid preparations of damiana, when mixed with water, act somewhat similar to the tincture of guaiacum—that is, by forming an opaque mixture or emulsion of a dirty greenish-white colour. A combination with a little liquor potassæ or water of ammonia forms a tolerably clear solution when diluted with water. The tincture of the chloride of iron changes the fluid extract to a dark bluish-green colour.

'Generally I prescribe the fluid extract of damiana in combination with equal parts of glycerine and syrup of tolu, or with some fruit syrup. Several of my patients have taken the drug in claret, Rhine wine, or lager-beer, to disguise its taste, while others prefer the cold fresh infusion. Frequently I have prescribed, as an adjunct, dilute phosphoric acid, from 10 to 15 drops with each dose of damiana. This addition renders it pleasant and easy to take.

'The following is the formula of the infusion which I have employed. Damiana leaves and flowers, two ounces; liquorice-root bruised, $\frac{3}{4}$ ounce; boiling water, sixteen ounces. Macerate for eight hours in a covered vessel, and strain. Dose: two to four ounces.'

VALENTI Y VIVO ON THE ANTAGONISM BETWEEN BROMIDE OF CAMPHOR AND STRYCHNINE.—Dr. Valenti y Vivo publishes in the *Siglo Medico* (quoted in *Paris Médical*, August 31, 1876), the conclusion of researches which he has made on this subject. Twelve dogs were poisoned by strychnine; some were saved by monobromide of camphor. The tetanic convulsions produced by the strychnine diminished in force and frequency under the bromide. The tonic convulsions became clonic, but a large dose of the bromide of camphor was necessary to combat the effects of the strychnine.

With an excessive dose of bromide, the united effects of the poison and the antidote produce death by syncope. The bromide acts on the great sympathetic, dilating the pupil and paralysing the heart. When death supervenes under the influence of the strychnine alone, the heart continues to beat after death, but when death is due to the bromide, no *post mortem* beatings of the heart are observed.

It is preferable to administer the bromide by the stomach in small and repeated doses; indeed, by hypodermic injection no result has been obtained.

DESCHAMPS ON THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM BY CYANIDE OF ZINC.—M. Deschamps of Liège has brought before the Medico-Chirurgical Society of that city the results which he has obtained in the treatment of acute articular rheumatism by cyanide of zinc (*Paris Médical*, September 7, 1876). In nine cases he administered the cyanide of zinc without ever increasing the dose beyond five centigrammes (0.77 grain) a day, in the following form: R. Cyanide of zinc, five milligrammes (0.077 grain); gum arabic and sugar of milk, of each, nine centigrammes (1.35 grains);

make one granule. Two to five granules a day, progressively.

M. Deschamps gives an account of these nine cases, and adds the following remarks. We must agree, if we abide by the preceding observations, that cyanide of zinc in small doses is a very valuable agent in acute articular rheumatism; under its influence, the pulse rapidly fell, sometimes to an inexplicable degree; the pains were rapidly diminished, but the temperature did not immediately come under this favourable influence. We also remarked that on the second or third day there was always an increase in the temperature, although the pulse maintained its ordinary rate or even fell below it.

These different effects of the cyanides, retardation of the pulse, lessening of the pain, and downfall of the temperature, have long been remarked: we can only conclude, then, that these observations have confirmed them by applying to acute articular rheumatism the physiological and therapeutic effects of cyanide of zinc.

Let us add that other reasons are in favour of this cyanide salt; its administration is easy, its elimination rapid, perhaps even cardiac complications are less frequent; we have, indeed, only had one well-marked case of endocarditis in the nine observations which have been recorded.

W. DOUGLAS HEMMING.

DUMAS ON ERUPTIONS PRODUCED BY QUININE.—In the *Journal de Thérapeutique*, no. 8, 1876, Dumas relates the case of a woman suffering from facial neuralgia, who, after having taken only 30 centigrammes ($4\frac{1}{2}$ grains) of sulphate of quinine, was seized with a paroxysm of asthma, coryza, fever, and violent itchiness over the whole surface of the body, accompanied by an eruption of urticaria, and further by a peculiar eruption formed by red spots like a scarlatina rash, and on some parts by papules. On four different occasions the patient suffered from the same symptoms after taking quinine.

G. THIN, M.D.

NICKLES ON THE ANTIPYRETIC USE OF QUININE.—In a paper read before a Cincinnati Society, the author gives a good *résumé* of our knowledge regarding the employment of quinine in large doses. He quotes Liebermeister as saying that he had given quinine in large doses in more than 1,500 cases of typhoid fever, and, besides, in hundreds of cases of pneumonia and other febrile affections, so that the number of single doses, varying from one scruple to forty-five grains, amounted to about 10,000. And not in a single case did he see permanent evil effects result, which could be ascribed to the action of the quinine.

NEAVE ON THE PREVENTION OF PITTING IN VARIOLA.—Although Dr. Neave does not allege that by any method of treatment 'pitting' can be certainly or entirely prevented, he has found that painting the face with tincture of iodine immediately upon the appearance of the eruption seems to have the effect of aborting the eruption to a great extent, many of the pocks never passing beyond the papular stage. His opportunities enabled him to experiment with a number of measures, and he found that carbolic acid and glycerine (gr. xv. to 3j.) rather increased the trouble and irritation. Carbolic acid with simple ointment was also a failure. Collodion caused intolerable itching and destructive scratching. Carbolic acid with linseed

oil (3ss. to ʒiv.) lessened the itching, but not the scarring. The experiment of painting one side of the face with collodion and the other with iodine resulted in favour of the latter in every way.

LEARY ON EUCALYPTUS GLOBULUS AS A DIURETIC IN DROPSIES.—Dr. J. B. Leary reports four cases in which the use of fluid extract of eucalyptus globulus, in doses of eight to ten minims as a diuretic, resulted most favourably. While patients have been taking it, they sometimes complained of a very severe congestive headache, accompanied with tinnitus aurium; their appetites were much better; though no tonics were prescribed, and in some cases the faecal movements were more fluid than usual.

LYLE ON SASSAFRAS AS AN ANTIDOTE TO VEGETABLE POISON.—The Cincinnati *Lancet and Observer*, for April, has a paper by Dr. A. W. T. Lyle, of Castleton, Indiana, in which attention is called to the statement by Dr. Thompson, of Nashville, concerning the antagonistic properties of sassafras to henbane and tobacco. Dr. Lyle mentions the case of a child four years old who had eaten stramonium flowers, and showed symptoms of poisoning. After the administration of emetics ten drops of oil of sassafras were given every half hour until six doses had been taken, when consciousness returned, and, after taking a dose of castor-oil, the child was playing the next day, and free from all pains or disturbances following poisoning.

LANGELL'S SECRET REMEDY FOR ASTHMA.—A writer in the *Peninsular Journal of Medicine* says an analysis of 'Langell's Asthma Remedy' shows that it is a mixture of ten or twelve parts of coarsely powdered belladonna leaves with one part of nitrate of potassium dried together. The packages contained about two ounces, and were priced at 1.25 dollars each. On igniting a portion on a plate, combustion takes place slowly, and the fumes are inhaled. It is said to give prompt relief, is much asked for, and can be sold in quantities for about half a dollar a pound.

THE RELATIVE VALUES OF CINCHONIDIA AND QUINIA.—In the July number of *New Remedies*, it is mentioned that the Medical Board of Bellevue Hospital, New York, had caused experiments to be instituted as to the relative merits of sulphates of quinia and cinchonidia. The latter salt was used, almost exclusively, for over a month in that institution. At the last meeting of the board, the various members on duty reported their experiences, and they seemed to be in the main tolerably agreeing with one another. The surgical members of the board declared cinchonidia to be a valuable tonic and antifebrile remedy, but found it to be totally inadmissible in severe surgical injuries, especially to the genito-urinary system, and in cases of shock, where it is apt to produce emesis, and in consequence thereof, or rather in connection therewith, severe congestive symptoms. In such cases cinchonidia had to be entirely abandoned, and quinia had to be resorted to. In purely medical affections, however, as in intermittents of all stages, pneumonia, etc., it was found to act with great promptness, although not quite so rapidly as quinia, and requiring a somewhat larger dose. Whenever the tonic effects of cinchona are desired to be produced, cinchonidia can with perfect reliability be substituted for quinia, and

the attention of physicians is especially directed to this fact, as it enables them to administer to patients in indigent circumstances a prompt and effective remedy at a considerably reduced expense. Hospitals and dispensaries, supported by public or private charity, will also do well to instruct their prescribing staffs to properly discriminate between cases which may be benefited by the dearer or the cheaper alkaloid. It will make a considerable difference in their annual expenditure.

PSYCHOLOGY.

BEARD ON THE NATURE AND PHENOMENA OF TRANCE.—In the *Archives of Electrology and Neurology* for May 1876 (quoted in the *Detroit Review of Medicine* for July), is given a careful and able study of trance. He describes trance as a passive state, conscious or unconscious, either physiological or pathological, in which the mind passes from the control of the will, and in the milder and conscious state acts through the senses in obedience to some prominent idea or external suggestion, with various mental and physical manifestations, and in the rarer and most advanced stages goes on to protracted suspension of the active vital functions.

Trance differs from sleep in the following general features. 1. The trance subject acts out his dream, while in sleep the dream does not cause any corresponding physical phenomena. 2. The performances of the trance are logical, coherent and consistent, while dreams are filled with extravagance and absurdities, which to the sleeper seem entirely proper. 3. In trance some of the senses are perfectly sealed. The loudest noises are not heard, the most fragrant odours are not observed, and there is no power of taste. Other senses may be unduly exalted. On the other hand, the soundest sleepers are awakened by loud noises or by sufficiently irritating the sensitive nerves. 4. Trance subjects are capable of responding to suggestions offered by a second party, or from any external source, and become consciously obedient to those suggestions. Sleepers present no such peculiarity. 5. In some forms of trance there may be double or divided consciousness. The subject, on coming out of the trance, has no recollection of his experience while in it. On again entering the trance, he resumes the experience of the previous attack where it left off, as though no active life had intervened. In sleep there is no such continuity of existence from one nap to another.

The symptoms of trance are these: 1. Closing of the eyes and fixity of position, with gradual loss of volitional power. 2. Flushing of the face and eyes, with sensible and cold perspiration, and coldness of extremities. 3. Sighing respiration and rapid pulse, with evidences of oppression and pain. 4. Mild or violent involuntary muscular motions. 5. Involuntary mental action, with exaltation or depression of the senses, and of the mental and muscular powers. 6. Illusions and hallucinations of various kinds. 7.

Various hysterical symptoms. 8. Profound sleep, with protracted suspension or diminution of active vital functions. He classifies trance as: (1) spontaneous; (2) self-induced; (3) emotional; (4) intellectual. Of the therapeutic uses of trances, he says they are not recommended as a regular procedure in important cases.

TOXICOLOGY.

POST ON POISONING BY CYANIDE OF POTASSIUM.—Dr. J. A. Post of Rochester, New York, relates in the *New York Medical Journal* for April, the case of Mr. R., aged forty-five, to whom he was called on January 31. He was labouring under symptoms of congestion of the brain, and died in about half an hour after being seen. He was a jeweller, and was in the habit of using cyanide of potassium and gold with an alloy. The vapour of the cyanide of potassium, he said, always produced in him the symptoms of brain-congestion. *Post mortem* examination, at 3 P.M., on February 1, showed the dura mater and arachnoid to be greatly congested. The pia mater was to all appearance perfectly normal, except an oval spot about an inch long by three-quarters of an inch wide, situated about one inch and a half above the internal occipital protuberance and one inch to the left. The internal surface of this spot throughout its whole extent was firmly connected to the surface of the brain, presenting the appearance of old inflammatory action. It did not penetrate the brain-substance, neither was it connected externally with the arachnoid. The arachnoid and dura mater immediately covering did not present evidence of any inflammatory action. This connecting substance presented the appearance of fibrous adhesions, and, when dissected, was found to be tough and to cut like cartilage. While dissecting this connecting link, the knife struck a spiculum of bone nearly half an inch in length, and about the size of a medium pin-point; this particle of bone was firmly pressed upon the brain, but did not penetrate the brain-substance. There was no serum or blood in the ventricles. The cerebrum was slightly congested, but the substance presented nothing abnormal. The cerebellum was very much congested, and quite soft. The contents of the chest and abdomen presented nothing indicative of disease. The various organs throughout the entire body appeared to be in perfect health. The case is a particularly interesting one on account of, 1. The action of the vapour of cyanide of potassium producing congestion and probably death; 2. The adhesion of the pia mater to the surface of the brain; 3. The spiculum of bone, which had undoubtedly been in that position for many years without producing cerebral troubles.

HJELT ON THE POST MORTEM APPEARANCES IN A CASE OF POISONING BY NITRIC ACID.—In the case of a woman, who died five hours after taking nitric acid, Dr. Hjelt (*Finska läkaresällskapet*

handl., Band xvii., and *Nordiskt Medicin. Arkiv*, Band viii.) found the following appearances. [The quantity and strength of the poison taken, and the symptoms during life, are not stated in the abstract.]

Both lips were of a brown yellow colour, and the epidermis was dry and desquamating. Below the lower lip were some small brownish irregular spots. Within the air-passage, below the vocal cords, were small dark red, blood-stained patches. On section of the lungs, a distinct odour of nitric acid was perceived. The mucous membrane of the mouth had a dirty grey appearance. The tongue was contracted; its surface was yellow grey; the papillæ at the base projected much; the epiglottis was swollen. In the fauces and upper part of the œsophagus the mucous membrane was turbid, thickened, and of a grey green-yellow colour, which extended downwards. The exterior of the lower part of the œsophagus was strongly injected. The stomach was contracted to the size of a large fist; its fundus was dilated. The mucous membrane throughout its whole extent was raised into broad ridges about two lines in depth, of yellow green appearance; between these were larger or smaller patches with a dark brown base, where the mucous membrane was totally destroyed. The remaining mucous membrane could be easily separated from the muscular coat, in the form of a greenish yellow, here and there reddish-brown, finely granular and very friable mass. This destruction of the mucous membrane was mostly found at the fundus. Near the lesser curvature, on the posterior wall, at the bottom of a portion deprived of mucous membrane was an oval opening about half a centimètre (one-fifth of an inch) wide, the edges of which were sharply defined internally, but uneven and swollen externally. The mucous membrane presented the above-named appearances as far as the pylorus, where also was found a smaller patch where the membrane was totally destroyed. In the stomach was a small quantity of yellowish-green fluid, containing solid particles: on testing, it gave the reaction of nitric acid. The mucous membrane of the duodenum presented the same appearance as the stomach for about three centimètres; the remaining portion was injected. The mucous membrane of the small intestine was full. The kidneys were firm; the cortical substance was dark red and injected; the glomeruli were filled with blood; the pyramids were streaky; the pelvis of the kidneys were injected. The blood was fluid, and had an acid reaction.

A. HENRY, M.D.

OBSTETRICS AND GYNÆCOLOGY.

TINKER ON A CASE OF EXTRA-UTERINE PREGNANCY.—The *Boston Medical and Surgical Journal* for May 18, contains the report, by Dr. Martin A. Tinker, of Brooklyn, of a case of extra-uterine pregnancy, in which portions of the fœtus were discharged *per rectum*.

The subject was a woman born in 1840, and married in 1859. She became pregnant in 1870. In May, 1873, Dr. Tinker first saw her. She was very weak, from a long-continued uterine discharge, which disappeared under treatment in about two weeks, while her strength only partially returned, with a very fair appetite. About two weeks after the uterine discharge had disappeared, a moderate diarrhœa supervened, which gradually increased,

while it became peculiarly offensive. All symptoms became aggravated quite regularly about every four weeks, and then would mostly subside during the interval. When on her feet for some time, or walking any considerable distance, her feet and ankles would become cedematous.

On July 13, 1873, while at stool, she perceived some large foreign body passing from her *per anum*; this was the left lower extremity of a full-grown foetus, firmly adherent to its ossa innominata by its ligaments, while the flesh was decomposed and gone from the ossa innominata, and from the knee downwards. From the hip to the knee the skin and flesh were *in situ*. Several other pieces of bones, etc., had been previously passed.

On making an examination *per vaginam*, Dr. Tinker found the parts healthy, the uterus pressed downwards and forwards somewhat, with a little anteversion, and not much larger than the virgin uterus. The os retained its relative position, but was slightly tilted backwards. The bladder was pressed forward, and the head of a full-grown foetus was felt posteriorly, resting upon the fundus of the uterus. On examination *per anum* he found a vertex presentation of the head, rather posterior to the fundus of the womb and above the recto-vaginal sulcus, and four or five inches above the anus there was an opening into the abdominal cavity about three inches in diameter, through which portions of the foetus could be distinctly felt.

No unusual symptoms occurred at this time, and the patient could walk about with very little inconvenience. As the head slowly descended into the recto-vaginal sulcus, the cedema increased, dysuria occurred, and reflex irritation of the stomach induced vomiting, which continued to the last.

The case progressed slowly, the head gradually settling down into the recto-vaginal sulcus, posteriorly to the uterus, pressing upon the rectum, and gradually filling the curve of the sacrum. At length, very painful hæmorrhoids were developed.

About the middle of October a large amount of decomposed matter had collected in the sulcus, below the head, which gradually ulcerated through into the rectum, near the anus, which opening continued to enlarge to the last. Through this opening the cranial bones could be distinctly felt overlapping each other.

On January 20, 1874, a large number of cranial and other bones, having become loosened, were removed with the aid of a small bullet-forceps, with much relief. Early in February the entire occipital, one parietal, and several other pieces were removed in the same manner, and an unusually large amount of decomposed matter passed immediately afterwards. The patient expressed herself as greatly relieved, and on the following day passed urine easily and retained food on her stomach.

After about one week the old symptoms gradually returned, and in a day or two increased rapidly, while the remaining portions did not settle down within reach as the others had done. On February 11, while at stool, and voiding a large quantity of decomposed matter, she fainted. She rallied in a few minutes, after which Dr. Tinker made a careful examination *per anum*, and found the remaining portions quite low, though not in the rectum, but mostly behind the uterus, and in the sulcus. No attempt could now be made to remove them. As she had passed no urine for twenty-four hours, the catheter was introduced, and the bladder found

empty. She gradually sank, and died on the same day.

At the necropsy, on examining the rectum, an opening was found in front, from two and a-half to three inches in diameter, about five inches above the anus, and another, somewhat larger, at the extreme lower portion near the anus. In seeking for this lower opening, the remaining portions of the fetal bones, etc., were removed, forming a mass about the size of a man's fist, which were retained in this position by the ureters, both of which were bared, and in front of the mass. Nothing morbid was found in the liver, spleen, kidneys, stomach, lungs, and other organs examined.

ERCOLANI ON SYPHILITIC DISEASE OF THE PLACENTA.—In the *Annales de Tocologie* (July 1876) Professor Ercolani describes a portion of the membranes of a syphilitic ovum of three months. It had the thickening usual at the epoch when the placenta is about to be formed; from its internal surfaces hung seven round excrescences, varying in size from a grain of maize to a cherry. Under the microscope they were seen to be formed of a network of vessels, supported by a yellow fibrous tissue. On vertical section it was seen that the yellow colour was superficial, and that the deeper stratum was red from vascularisation. The diversity of colour depended on the vascularisation; in the red portions the vessels were hollow, and the blood circulated freely; in the decolourised periphery the vessels were obliterated by proliferation of the internal vascular epithelium.

BROCA ON A SACRO-COCCYGEAN FETAL TUMOUR.—In the *Annales de Tocologie*, for July, M. Broca reports a case of a congenital tumour in the sacro-coccygean region of a girl, aged fifteen, in which bone could be felt. It was recognised as a fetal tumour, and was removed. M. Broca carefully dissected the growth away, and found it to be nourished by a continuation of the sacra media artery, which was tied. The tumour consisted of several small cysts, containing the following distinct anatomical elements: mucous tissue with ciliary epithelium, bone, cartilage, connective tissue, and muscle; no nervous tissue appeared. This abnormality, M. Broca remarks, comes under Geoffroy Saint-Hilaire's class of double endocymian monsters.

FANCOURT BARNES, M.B.

LEALE ON FATTY DEGENERATION OF THE PLACENTA AS A CAUSE OF DEATH IN THE FETUS.—At a meeting of the New York Academy of Medicine, (*New York Medical Record*, June 17.) Dr. C. A. Leale read a paper upon the above subject. Fatty degeneration was regarded as the result of a defect, and not disease of the nutrient process. Such defect might be developed in connection with syphilis, phthisis pulmonalis, scrofula, apoplexy, and other conditions, and give rise secondarily to fatty degeneration.

In a case, of which the history was given, premature labour had been advised by Dr. Fordyce Barker as a measure to be adopted for securing the delivery of a living child; and the symptoms of alarming prostration on the part of the mother, together with the feebleness of the fetal heart, were the indications which decided the time when Dr. Leale should execute the plan recommended. The child was exceedingly feeble when born, but its life was saved by dint of perseverance in the most careful and tender nursing. The placenta was found so far advanced

in fatty degeneration as to be more than two-thirds useless, there being no doubt in this instance that the life of the child would have been sacrificed if it had been permitted to go the full term of uterogestation. The conclusions arrived at were mainly as follows.

Fatty degeneration of the placenta was the cause of death in the fœtus more commonly than was generally supposed; its access might be insidious and its progress slow.

The causes were uterine and ovarine anomalies, insufficient vitality of the ovule, disease of the ovule, insufficient vital force in sperm, disease of sperm, emotional causes, or shock causing paralysis or incomplete detachment of placenta, etc.

The varieties were tuberculous calcareous degeneration with fibrinous deposits, anæmia with atrophy, simple fatty degeneration, degeneration from apoplexy, scrofula, syphilis, and waxy degeneration associated with leucocythæmia.

As a measure for securing the delivery of a living child in cases in which fatty degeneration of the placenta was suspected, and constitutional treatment had failed or was not indicated, where the life of the mother or the child was endangered by delay, Dr. Leale recommended the induction of premature labour at about the thirty-sixth week of uterogestation, in accordance with the suggestion made by Dr. Barker in the case to which allusion had been made.

ADAMS ON A CASE OF RUPTURE OF THE SYMPHYSIS PUBIS DURING LABOUR.—Dr. Z. B. Adams reports a case of this accident in the *Boston Medical and Surgical Journal* for July 6. The patient was a primipara, medium sized, well formed, forty-two years old. The liquor amnii escaped twenty-four hours before labour began. The head was for several hours fixed in the brim. The os was rigid, undilated. The presentation was vertex, in the second position. The bladder was emptied, and the forceps applied. Expulsive pains were strong; and traction upon instruments in the direction of the axis of the brim being made at same time, the symphysis pubis gave way with a loud crack. The forceps did not break, nor slip, nor twist. Labour was rapidly completed. Four weeks after the accident, on examination under ether, complete separation of the symphysis was found; a space of two inches between the ragged edge of the bone upon the right side and the torn ligament and fibro-cartilage of the left, with laceration of the anterior wall of the bladder, and rent into the vestibule. The urethra, entire, was very large, admitting one finger readily. The posterior wall, fundus, and base of the bladder were uninjured. The vagina was everywhere whole, although its rectal surface showed irritation from dribbling urine. The os uteri, rather high up, was healthy in feeling, and the sound passed into the fundus uteri two and one half to three inches without the slightest difficulty or appearance of uneasiness. The brim of the pelvis and the promontory of the sacrum, carefully examined, showed nothing abnormal.

DERMATOLOGY.

FOOT ON A CASE OF SCLERODERMA.—Dr. A. W. Foot (*Dublin Journal of Medical Science*, July, 1876) describes an interesting and typical case of scleroderma, in which the contraction of the skin of the face was greatly marked. The integument became much more pliable after diligent inunction with cod-liver oil.

AUBERT ON HERPES TONSURANS IN PATIENTS UNDER TREATMENT FOR FAVUS.—Aubert (*Lyon Médical*, no. 35, 1876), has twice observed black points like comedones persisting after the appearances of favus had yielded to treatment. They were shown by the microscope to consist of hairs affected by spores. When inoculated on the arm of a healthy man, hairs infiltrated with spores were found after thirty-seven days, but there were no favus-crusts. Three inoculations on rats failed, favus being readily inoculable on these animals. Hence Aubert concludes that the hairs were affected with the spores of herpes tonsurans independently of the favus, and calls attention to the dark points in a diagnostic point of view.

KOLACZEK ON CIRCUMSCRIBED ATROPHY OF THE SKIN.—Erasmus Wilson has recorded two cases of skin atrophy in the upper part of the face and forehead, and has termed the affection atrophía neurotica. In one case the cause was a blow on the forehead, and a white line over the supraorbital nerve was after several years followed by depression and anæsthesia; in the other, a similar atrophy followed violent sneezing. Dr. Kolaczek (*Deutsche Medicinische Wochenschrift*, no. 32, 1876) observed a similar case in a girl, aged twenty. She fell against the corner of a stove when eleven years old. After two years, a yellow spot was observed on the right side of the forehead, close to the middle line. This spread upwards and downwards, and eventually the skin became thin, wrinkled, and somewhat shining. Not only the skin, but the subjacent bone was partially atrophied. Sensation was diminished over the part. The position anatomically corresponded to the course of the frontal artery and vein, as well as the middle branch of the frontal nerve. The patient referred the condition to the blow sustained when she was a child.

OPHTHALMOLOGY AND OTOLOGY.

GRAND ON SOME RARE CASES OF OCULAR PATHOLOGY.—Dr. Grand of Saint-Étienne (Loire) relates the following cases in the *Lyon Médical*, September 24, 1876.

1. *Corneal Fistula from Prolonged Lodgment of a Foreign Body.*—A metal-founder was seen six days after an accident, with a particle of metal buried deeply in the centre of his cornea. Many fruitless attempts were made to remove it, and after treatment with atropine and warm fomentations, there being little or no irritation, the man was allowed to resume his work. At the end of a month his vision suddenly became disturbed, and the eye ran tears, without being painful. On examination Dr. Grand found the anterior chamber wanting, and a fistulous opening at the seat of injury. The little piece of metal had, by exciting suppuration round itself, caused a perforation of the cornea, which its presence kept open. Renewed attempts at removal were unsuccessful. Considerable inflammation ending in iritis and synechiæ followed, which yielded to treatment, and the central opening began to heal, enclosing the remains of the metal in the corneal tissue.

2. *Fragment of Steel lodged for Five Months in the Corneal Lamina, without marked Inflammatory Reaction.*—This case offers a remarkable instance of the length of time which the cornea will tolerate the presence of a foreign body. In a young man a piece of steel, eight millimètres in length, after having traversed the cornea obliquely throughout nearly its entire thickness, remained imbedded for five months, without producing either marked inconvenience or appreciable inflammatory symptoms. At the end of this time, whilst it was in process of being thrust out by the tissues, a minute point protruded, and by its continual irritation of the eyelid in its passage over it, caused great discomfort. This stopped the man's work, and sent him to Dr. Grand, who seized the foreign body with a fine pair of forceps, and drew it out.

3. *A Case of Parenchymatous Keratitis.*—A pale, weakly, cachectic boy, the fifth child of a mother who contracted syphilis from a foster child after her first confinement, had been affected for six months with parenchymatous keratitis occupying the whole extent of both corneæ. The incisor teeth were notched, the corneæ greyish-white without vascularity. He was ordered warm compresses, calomel insufflations, and iodide of potassium (1 grain daily), with cod-liver oil. In three weeks great improvement had taken place, and in six weeks only some points of faint greyish infiltration remained. This case is cited to show that parenchymatous keratitis is not always of such long duration nor so rebellious to treatment as is believed, and further, that the absolute proscription of irritants in its local treatment is not warranted by experience.

4. *Complete Cure of an Old Detachment of the Retina, without Surgical Interference.*—After referring to cases of this kind, reported by American ophthalmologists, Giraud-Teulon, of Paris, and others, as evidence that the prognosis of retinal detachment is by no means to be considered as absolutely unfavourable, especially when the detachment is partial, Dr. Grand relates the following case. A lady having a myopia of $\frac{1}{4}$ in each eye, suffered

from a detachment of the retina in the right, which in six months had involved the whole of the inner half of the field of vision. Professor Dor, of Berne, had already seen her, and ordered Heurteiou's leech to the right temple; this was followed by benefit which lasted four days. The abstraction of blood was repeated freely, and the patient was kept lying upon her back, in a darkened room, for thirty-six hours. On examination with the ophthalmoscope, at the end of this time, the retina was found to have become replaced throughout its extent, excepting a small piece at the lower part, and the field of vision had recovered its normal extent, but opposite to the replaced retina objects had a confused look. This treatment was repeated from time to time, and supplemented by veils, coloured glasses, and the instillation of atropia. At the time of reporting the patient read $1\frac{1}{2}$ Snellen at four inches, the visual field was normal, with some slight diminution of acuity in the upper and internal part, sight was slightly clearer on rising in the morning than in the evening, and for three months the condition had been perfectly stationary. Dr. Grand draws special attention to the efficacy of the leechings (Heurteiou's), each application having brought about a replacement of the retina.

5. *Paralysis of the Superior Oblique.*—The patient, a clerk, had all the symptoms of paralysis of the superior oblique of the right eye, in all probability the result of cold. He was treated first of all by stimulating frictions round the orbit, iodide of potassium, and, in order that he might continue his work, a prism of 6° , with the base directed downwards and slightly outwards. Four days afterwards electricity was used. Dr. Grand employed the continuous current from a pile of five or six elements, with sulphate of copper and sulphate of zinc (Trouvé). The copper pole was placed upon the forehead, and the zinc pole moved about the inner angle of the eye. After half a minute at most of electrification, the diplopia disappeared completely. This improvement lasted the first time about two hours. The treatment was continued daily for ten days, at the end of which period improvement was maintained for five or six hours. Although, however, the diplopia diminished, it did not disappear, and the following frictions were used round the orbit; tincture of iodine twenty grammes, strychnia one gramme; and two pills containing extract of nuxvomica were administered daily. At the end of a week all traces of the paralysis had disappeared.

SALTINI ON THE SUBCUTANEOUS INJECTION OF CALOMEL IN SYPHILITIC IRITIS.—In a paper published in the *Annali di Ottalmologia* (vol. v., fasc. 2 and 3) Dr. Giulio Saltini discusses the question whether the rapid cures of syphilitic iritis by subcutaneous injections of calomel, reported by Drs. Quaglino, Flarer, De Magri, and others, have been due exclusively to the antisiphilic action of the remedy, or to the solvent action of mercurials in general, or to the revulsive influence which circumscribed suppurations in the temporal region exercise upon certain ocular affections. He furnishes most careful notes of five cases of syphilitic iritis which were treated in the Modena Clinique, under the care of Dr. Manfredi, where the affection yielded most rapidly to the subcutaneous injection of calomel in the temple, without any apparent effect being produced upon the general syphilitic symptoms. He reports, in addition, four cases, one of simple keratitis, two of ulcerative kera-

titis, and one of rheumatic iritis, in all of which relief speedily followed the use of calomel subcutaneously. From his observations he draws the following conclusions.

1. In the present state of scientific knowledge, the vaunted efficacy of injections of calomel in the treatment of constitutional syphilis has not been satisfactorily proved.

2. The great advantages derived from injections in the temples, in the cure of syphilitic iritis, should most probably be referred to a local action of calomel, whether solvent or revulsive, or to both actions combined, as Dr. Quaglini has judiciously observed, and as is also proved by the efficacy, above reported, of this new proceeding in the cure of non-syphilitic ocular affections.

3. To establish definitively this local action of calomel injections, some experimental researches should be undertaken, especially with regard to the effects that may be obtained by the injection of insoluble substances, such as finely powdered charcoal or sawdust, in the cure of certain eye-diseases.

LLOYD OWEN.

LADREIT DE LACHARRIÈRE ON THE EMPLOYMENT OF IODISED PREPARATIONS IN THE TREATMENT OF DISEASES OF THE EAR.—Dr. Ladreit de Lacharrière has an article on this subject in the *Annales des Maladies de l'Oreille et du Larynx* for July, 1876, an abstract of which appears in the *Paris Médical* for August 3. He makes the following remarks. Otorrhœa is the most frequent of the affections of the ear, engendered by the scrofulous diathesis. It manifests itself most often in childhood, following typhoid or the eruptive fevers, but it may persist throughout life. Even to this day some medical men consider these discharges as salutary emunctories; they speak of serious results which have followed the sudden suppression of aural discharges, and dare not interfere with them, counting on puberty effecting a cure. But on the contrary these discharges have no tendency to spontaneous cessation, and we should endeavour to stop them as soon as possible, before the work of ulceration has caused loss of the organ and occasioned an inevitable deafness.

It is when these discharges have had a certain duration, when the secretion seems to have its origin from the surface of the periosteum, or even in the bony tissue itself, that we should have recourse to iodine or its compounds. The author employs a solution of iodine, of which the following is the formula, and which he uses night and morning as an injection: \mathcal{R} . Water 1,000 parts; tincture of iodine, thirty parts; iodide of potassium, four parts.

Following subacute inflammation of the middle ear, simple engorgement of the ossicles has been observed. Left to itself, the effusion is rarely absorbed; the ossicles become less mobile, and this fixity shows itself outwardly by a great projection of the handle of the malleus. The hearing becomes more and more obtuse, and the patient suffers from musical buzzings of the most painful nature. This deafness is frequently observed in gouty people. Very often it is found useful to drop into the auditory meatus a few drops of the following solution: \mathcal{R} . Rose-water, 300 parts; iodide of potassium, two parts. These applications have sometimes caused a slight irritation of the auditory meatus, but they have also often sufficed to bring about absorption of the morbid deposit and a return to the normal condition.

A very useful means, especially in those of the lymphatic temperament subject to catarrhal inflammations of mucous membranes, consists in projecting into the cavity of the tympanum the vapour of iodine at the surrounding temperature. To do this it is sufficient to cause, by the aid of Richardson's apparatus, a current of air to pass either through a small quantity of tincture of iodine or simply over its surface.

In simple catarrh of the tympanic cavity with swelling of the mucous membrane, and deafness, the balsamic and sulphurous preparations form the basis of the most useful indications. Nevertheless, moderate revulsion is often necessary, and it has then been found useful to apply an ointment, of which the following is the formula, over the mastoid processes: \mathcal{R} . Lard, thirty parts; tincture of iodine, one part; iodide of potassium, two parts.

Diseases of the nasal fossæ, and of the pharynx, frequently react upon the ears; in this case it is only as an adjuvant that the preparations of iodine can act, but according to the author these affections are cured most completely and most rapidly when the mucous secretions have been increased for some days by the use of iodide of potassium. As for acute syphilitic osteitis and periostitis, the use of iodide of potassium in these cases is very clearly indicated.

BOUCHERON ON THE TREATMENT OF SYMPATHETIC OPHTHALMIA.—Dr. Boucheron recently read before the Société de Biologie a paper in which he proposes to substitute for enucleation of the globe of the eye section of the ciliary and optic nerves behind the eye. (*Paris Médical*, July 13, 1876). The following is his method of procedure. He divides the conjunctiva and the capsule of Tenon between the external and superior rectus about a centimètre from the cornea, and then with curved scissors penetrates between the capsule and the eye. Then drawing forward the globe seized near the cornea with forceps, he stretches the optic nerve so that the scissors touch it as a rigid cord. The optic nerve is divided, and the ciliary nerves and arteries are dealt with in the same manner, by little cuts of the scissors. A little bleeding ensues, which is easily arrested by slight pressure on the eye. In order to be sure that the operation has been perfectly done, and that none of the ciliary nerves have been permitted to escape, after the section of the optic and ciliary nerves, the opening in the capsule is enlarged and the sclerotic seized by forceps in the posterior hemisphere of the eye. This posterior hemisphere may then be easily turned forwards, so that the divided optic nerve is brought into view. The ciliary nerves may then be divided with ease, as they form a plexus round the optic nerve. Thus nothing can escape, and the operation is performed perfectly. He avoids cutting the insertion of the recti muscles, in order to preserve the anterior ciliary arteries, branches of the muscular arteries, and branches of the ophthalmic. Thus no obstacle is opposed to the re-establishment of the circulation in the eye by the anterior vascular system. Besides this, by retaining the recti muscles he preserves to the eye its normal position and movements.

The author proceeds to detail experiments which he has performed on the dog, the rabbit and the guinea-pig. He also relates a certain number of observations of cases in which the optic and ciliary nerves had been divided by wounds. Now, in all

these cases, unless some other cause of weakening was joined to the wound, he did not observe any grave lesions of the refractive media.

The indications for the section of the optic and ciliary nerves may be given in a few words. This operation should be substituted for enucleation in all cases, unless suppuration of the eye is certain. But the great advantage of this operation is its power of being employed as a preventive measure. The International Ophthalmological Congress in 1872 accepted, in principle, that enucleation of a wounded eye should be performed immediately if one wished to make sure of warding off often irremediable attacks of sympathetic ophthalmia. This radical and terrible measure, however, has not come into ordinary use. It is hoped that the operation just described, so simple, so inoffensive, and so conservative in its nature, will be able to afford to patient and practitioner important services.

FOREIGN UNIVERSITIES.

UNIVERSITY OF GENEVA.

The University of Geneva grants the degrees of Bachelor in Medical Science and Doctor of Medicine.

The following classes of persons are admitted as students in the Faculty of Medicine; 1. Bachelors in Letters; 2. Bachelors in Science; 3. Students who have attended during two years lectures in the Section of Philosophy, and have undergone the examinations at the end of each year; 4. Pupils from the Classical Section of the Gymnasium, with certificates of studies; 5. Swiss and strangers who give evidence of their studies by means of diplomas or certificates; 6. Persons who undergo satisfactory oral examinations in the subjects comprehended in the classical section of the Gymnasium. Persons who furnish evidence that they have studied abroad, for a year at least, in a corresponding faculty, may be inscribed in the Faculty of Medicine.

The course of study is as follows:—*First Year: Winter Session:* Botany (first part); Physics (first part); Comparative Anatomy or Zoology; Inorganic Chemistry; Practical Comparative Anatomy. *Summer Session:* Botany (second part); Physics (second part); Comparative Anatomy or Zoology; Organic Chemistry (first part); Practical Chemistry; Botanical Excursions. *Second Year: Winter Session:* Descriptive Anatomy (first part); Physiology (first part); Organic Chemistry; (second part); Dissections. *Summer Session:* Descriptive Anatomy (second part); Physiology (second part); Practical Chemistry and Practical Comparative Anatomy. (Students are recommended to attend in addition courses of other subjects, such as Astronomy, Geography, Physics, Mineralogy, Geology, etc.) *Third Year: Winter Session:* Descriptive Anatomy (third part); Normal Histology; Dissection. *Summer Session:* Regional Anatomy; Embryogeny; Supplementary courses on subjects of the preceding years, on which the student's knowledge is weak;

Practical Physiology, Histology, Comparative Anatomy, and Chemistry. (The examination for Bachelor in Medical Sciences is now undergone). *Fourth year: Winter Session:* General Pathology; Internal Pathology; External Pathology; Dissection of Regions; Medical and Surgical Hospital Practice. *Summer Session:* Special Pathological Anatomy; Pathological Histology; Internal Pathology; External Pathology; Pharmacology; Medical and Surgical Hospital Practice; Exercises in the Laboratory of Pathological Histology.—*Fifth Year: Winter Session:* Therapeutics; Hygiene; Legal Medicine; Theory of Obstetrics; Internal Pathology; External Pathology and Operations; Medical and Surgical Hospital Practice.—*Summer Session:* Therapeutics; Legal Medicine; Internal Pathology; External Pathology; Medical and Surgical Hospital Practice; Operations.—*Sixth Year: Winter and Summer Sessions:* Medical, Surgical, and Obstetrical Hospital Practice; Polyclinic; Ophthalmology, Psychology, etc. Repetitions preparatory to the examination for the Doctorate.

Persons who have satisfied the conditions laid down regarding the admission of students to the Faculty of Medicine may become candidates for the degree of Bachelor in Medical Science. Students who have undergone the recognised annual examinations in the Faculty of Medicine or of Sciences are exempt from oral examinations in the subjects in which they have already been examined; provided that the examinations have been undergone not more than two years previously. Persons who produce diplomas or certificates giving evidence of their studies may be exempted from further examinations in the subjects in which they have already passed.

The following may become candidates for the degree of Doctor of Medicine: 1. Bachelors in Medical Science; 2. Persons who produce diplomas or certificates indicating that they have gone through an equivalent course of study. There are five examinations for the degree of Doctor of Medicine.—*First Examination:* Human Anatomy and Histology; Physiology; Pathological Anatomy and General Pathology; a Necropsy, for which one hour is allowed; making an Anatomical Preparation, for which four hours are allowed.—*Second Examination:* Medicine; Surgery; Operative Surgery; three Operations, and Application of Bandages.—*Third Examination:* Hygiene; Therapeutics; *Materia Medica* and Pharmacology; Legal Medicine; a Medico-Legal Report on a real or supposed case, for which one hour is allowed.—*Fourth Examination:* Clinical Examination of two medical and two surgical patients and of one case of labour (fifteen minutes being allowed for each case); Obstetrics, with operations on the mannikin; Discussion on each Clinical Case: Written Commentary on a Medical and a Surgical Case, two hours being allowed.—*Fifth Examination:* Defence of a printed Dissertation, in the French language, on a subject in medical science chosen by the candidate. The dissertations must be previously communicated to the Faculty.

The examinations are public. Those for the degree of Bachelor are held at the beginning and end of the University year, and in the interval between the sessions. Applications for admission must be made to the Dean of the Faculty of Medicine eight days before the day of examination. The examinations for the degree of Doctor take place, on the demand of the candidates, at times determined by the Faculty.

The following courses of lectures will be delivered by the Faculty of Medicine. *Winter Session.*—Normal Anatomy, Professor Laskowski; Physiology, Professor Schiff; Histology, General Pathological Anatomy and Physiology, and Necropsies, Professor Zahn; Clinical Medicine, Professor Revilliod; Clinical Surgery, Professor Julliard; Clinical and Theoretical Midwifery, Professor A. Vaucher; Polyclinic, Professor Vulliet; Internal Pathology, Professor D'Espine; External Pathology and Operative Surgery, Professor Reverdin; Therapeutics, Professor Prevost; Hygiene, Professor Dunant; Pharmacology, Professor Brun; Psychiatry, Dr. Olivet. The following are free courses: Gynaecology, Dr. Gautier, Dr. Devrient, and Dr. Cordés; General Pathology, Dr. Durante; Ophthalmology, Dr. Barde and Dr. Haltenhoff; Accouchements, Dr. Odier; Balneotherapy, Dr. Glatz; Functions of the Central Nervous System, Dr. C. Geib; Dental Medicine and Surgery, Dr. Guillot. *Summer Session.*—The same subjects are taught (other departments being taken) as in winter, except Histology, General Pathology, Pharmacology, and Balneotherapy, and the following are given in addition: Special Pathological Anatomy, Professor Zahn; Legal Medicine, Professor Gosse; Pathology of the Urinary Organs, Dr. E. Martin; Otology, Dr. Colladon.

The winter session commences on October 16, and ends March 16, 1877; the summer session commences March 25, and ends June 22.

UNIVERSITY OF BRUSSELS.

By the regulations of the University of Brussels, British and other medical practitioners, provided with proper qualifications, are admitted to examination before the faculty for the degree of M.D. Residence is not required from such as are unable to absent themselves long by reason of their professional occupations.

No degrees, however, are granted *in absentia*, and candidates must come over in person and have their names inscribed in the books of the University. The fees are, for inscription of name, 215 fr. (8*l.* 12*s.*); for examinations, 315 fr. (12*l.* 12*s.*); for legislation of diploma, 10 fr. (8*s.*); total 540 fr. (21*l.* 12*s.*) The examination consists of three parts: 1. General Therapeutics, including Pharmacodynamics (proportions of doses), Special Pathology and Therapeutics of Internal Diseases, General Pathology, and Pathological Anatomy. 2. Surgical Pathology, Theory of Midwifery, Public and Private Hygiene, Medical Jurisprudence. 3. Examination at the Hospital of one or two patients under Medical and Surgical Treatment; Examination in Midwifery, consisting in Obstetrical Operations on the *mannequin* (model of pelvis); Examination in Operative Surgery consisting in some of the usual operations on the dead subject, such as amputation, ligature of an artery, etc.

Great importance is attached to practical knowledge, but candidates must also prove that they possess positive theoretical science.

Examinations take place at any time between October 15 and June 20, except during the Christmas and Easter vacations. They are *viva voce* and written, but candidates may be exempted from the latter and confine themselves to the *viva voce* tests. Candidates must exhibit their qualifications or diplomas.

The three examinations may be got through in a week, allowing a day's interval between each test. Saturday is the most eligible day for arriving, for candidates for whom time is an object. The delay of a week is, however, never exceeded by more than a day or two.

The examinations are conducted in English through the medium of an interpreter, for such candidates as are not familiar with the French language.

The degrees granted by the faculty are merely scientific titles, and do not confer the right to practise medicine in Belgium.

UNIVERSITY OF STRASSBURG.

The following is an extract from the regulations of the University of Strassburg relative to Degrees in Medicine.

Any person desirous of obtaining the Degree of Doctor of Medicine can only be admitted to graduation on fulfilling the following conditions. *a.* If he belong to the German empire, he must have completed the academical four years' course of study of Medicine, or of the Natural Sciences. By an unanimous decision of the Faculty, one or two Sessions may be omitted. Foreigners desirous of graduating are not required to have passed through the four years' course, if they produce proof of having received instruction equivalent to the course of study in the Medical Faculties of Germany. *b.* He must present a scientific essay (dissertation) composed by himself. *c.* He must undergo the Faculty examination. *d.* He must pay the prescribed fee of 100 thalers (about 15*l.* 15*s.*).

In his application for graduation, which must be addressed to the dean, the candidate must produce the evidence referred to in *a*, and forward a scientific memoir on some department of medicine, with a written assurance that it is absolutely his own composition.

If the dissertation receive the approval of the Faculty, the candidate is admitted to examination.

The examination is conducted by the ordinary professors, and consists, as a rule, of an oral theoretical examination in all important departments of medicine. If the candidate fail to give satisfaction in the oral examinations, he must, in order to obtain the degree of doctor, again undergo the examination after a time to be determined by the Faculty, but he is not required to present a second dissertation.

In the case of candidates who have already passed the State examination, a colloquy before three members of the Faculty may, by the unanimous decision of the Faculty, be substituted for the oral examination.

Degrees in Medicine are not conferred on absent candidates.

The fee of 100 thalers is to be paid to the dean at the time when the candidate offers himself. If the scientific dissertation be rejected, the candidate receives the whole fee back. If the dissertation be approved, but the candidate fail in the examination, the fee is not returned to him, but, when he is again admitted to examination, only half the fee is required.

After the faculty examination has taken place and the dissertation has been printed and published, the candidate is formally admitted to the degree of Doctor by the issuing of a printed diploma, the

names of the successful candidate being announced on the black board.

The candidate has to bear the expense of printing the dissertation and of the diploma.

There is no public ceremony, and no oath is administered.

The lectures for the session 1876-77 begin on Monday, October 16. Matriculation takes place on the first four Wednesdays of the season, from twelve to one o'clock. After the end of these four weeks, the rector can allow matriculation only on special grounds. Any one desirous of matriculating as a student, and attending the lectures and other instruction given in the University, must, on his arrival in Strassburg, communicate with the Secretary of the University, in order to be inscribed. Other persons desirous of attending the lectures must obtain permission from the respective teachers, and must then at once communicate with the Secretary of the University.

The following are the professors and teachers of the University, with the courses of instructions which they will give in the coming academical year. *Ordinary Professors.*—Dr. Waldeyer: Human Systematic Anatomy (first part); Comparative Anatomy of the Apparatus of Digestion, Circulation, and Respiration; History of Development; Dissections; Instruction in Special practical work in the Anatomical Institute.—Dr. Jössel: Dissections; Osteology and Syndesmology; Topographical Anatomy of the Extremities, Head, and Neck.—Dr. Goltz: Experimental Physiology of the Vegetative Organs and Organs of Sense; Exercises in the Physiological Laboratory.—Dr. Hoppe-Seyler: Physiological and Pathological Chemistry; Practical Course of Medical Chemistry; Laboratory Instruction in Physiological Chemistry; Hygiene.—Dr. Schmiedeberg: Experimental Pharmacology and Therapeutics; Toxicology; Instruction in the Pharmacological Laboratory.—Dr. von Recklinghausen: General Pathological Anatomy and Physiology; Malformations; Demonstrations of Pathological Anatomy, with *Post Mortem* Examinations.—Dr. Kussmaul: Medical Clinic; Medical Polyclinic; Diseases of the Organs of Circulation; Diseases of the Stomach.—Dr. Lücke: Special Surgery, first part; Surgical Clinic and Polyclinic.—Dr. Guserow: Theory of Obstetrics; Diseases of New-born Children; Obstetric and Gynaecological Clinic.—Dr. Strohl: Legal Medicine; Forensic Psychiatry.—Dr. Wiegner: History of Medicine, first division; Clinic of Syphilitic and Cutaneous Diseases.—Dr. Aubenat: Labours; Pathology of Pregnancy.—Dr. Jolly: Theoretical Psychiatry; Psychiatric Clinic.—*Extraordinary Professors.* Dr. Laqueur: Clinic of Diseases of the Eye; Course of Ophthalmoscopy for advanced students.—Dr. Kohts: Medical Polyclinic; Children's Polyclinic and Diseases of Children. *Private Teachers.* Dr. Kuhn: Otorrhoea; Clinic of Diseases of the Ear.—Dr. Friedländer: Diseases of the Organs of Respiration.—Dr. Rähmann: Theory of Ophthalmic Surgery, with demonstration of the more important cases of Disease; Course of Ophthalmology.—Dr. Tiegel: Physiology of the Muscles; Electro-Physiology.—Dr. Sonnenburg: Dislocations and Fractures; Instruction in Bandaging and Operating.

SOCIETIES.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The following papers were read in the Department of Anatomy and Physiology, Section of Biology, at the recent meeting in Glasgow.

The Physiological Action of Vanadium.—Mr. John Priestley stated that the results of this research were embodied in a paper presented to the Royal Society of London, an abstract of which appeared in the last volume of the *Proceedings*. Vanadium was a metal that had been carefully examined by Roscoe, but nothing was ascertained in that examination as to its physiological action. It belonged to the group of metals including arsenic, antimony, and bismuth, and its atomic weight was 51.2, very nearly resembling chromium. It formed four series of compounds, and numerous experiments had been made as to the action of solutions of the metal on physical organisms. It was found to be an intense irritant poison, rapidly causing death, which was accompanied or preceded by paralysis, convulsions, and supervening drowsiness. It appeared that all the solutions except those that were extremely diluted acted injuriously on such organisms as the bacteria, germinating seeds, fungi, and so forth. It was applied to rabbits, pigs, cats, dogs, pigeons, and frogs, and the results might be thus briefly stated.—The solution was injected into the skin, into the veins, and into the alimentary canal, and in all cases the results were similar. The symptoms were first of all paralysis of motion, next convulsions either local or general, and then rapidly supervening drowsiness, congestion of the alimentary mucous membranes, the presence of a fluid mucus in the intestines after death, and certain changes of respiration, and, coincidently, a falling temperature and feebleness of pulse. Experiments on respiration, circulation, and the nervous system had been made at length. Experiments on a rabbit showed that, both before and after the division of the nerve-centre, vanadium caused in the first instance a stimulation, and in the next a depression of respiration. This was due to the action of the poison on the nervous centre of the medulla. It was also found, by injections made under the skin and into the veins, that vanadium caused a diminution of blood-pressure and irregularity of pulse. When a frog had been poisoned by injected vanadium, it was found that when the reflex irritability was entirely abolished, and the muscles and nerves were tested by electricity, the work done compared with the normal work of muscles not poisoned, did not show any difference.—Professor Gamgee read a paper on the action of vanadium upon the intrinsic nervous mechanism of the frog's heart. He said that he had found certain definite phenomena following the injection of vanadium. The ventricle came to a stand-still when a certain quantity was injected, but where the quantity was exceedingly small, the ventricular systole was rendered slow, the auricles began to beat more slowly, and finally the heart stood still. The inhibitory centres of the heart connected with the auricles were not affected, but the vagus lost its power of inhibiting the ventricle. It might be suggested that this remarkable action of the poison resulted from the fact, that vanadium did not act on the inhibitory fabric connected with the vagus or centres of the auricles, and that there was one in-

hibitory centre of the ventricle quite distinct from the inhibitory centres of the auricles. He should be loth to formulate such a suggestion. Physiologists knew nothing of the inhibitory centres in the heart; they only surmised their existence to account for the phenomena exhibited in cases of poisoning by nicotine and other poisons. The researches of Mr. Priestley had shown that vanadium was not a muscular poison, because after it had been injected the muscles were found to retain all their irritability. He (Professor Gamgee) was not prepared to say to what extent the phenomena in the heart were really due to the influence exerted on the contractile substance of the heart. Digitalis, veratrine, and antiar had been looked upon as muscular poisons, but he should be inclined to think that they were not, because, while they affected the contractions of the ventricle, they did not affect the contractions of the auricle. No doubt vanadium must be regarded, like digitalis and other poisons, as a poison of the muscular substance of the heart, but more particularly as a poison of the nervous apparatus of the heart. Dr. Gamgee next gave a summary showing the difference in the poisonous activity of the orthophosphoric, metaphosphoric, and pyrophosphoric acids. He pointed out that, although all the vanadates were poisons in the animal economy, they differed considerably in intensity; and having given an account of the results of experiments with different acids, he arrived at the conclusion that the metaphosphoric acid was not so poisonous as the pyrophosphoric, and that there was a great relationship between all these phosphates and the corresponding vanadates. He also stated that not only did the pyrophosphoric acid produce death very rapidly when administered in certain quantities, but that it might be made to produce the same result very slowly. Professor Gamgee also summarised the results of experiments, showing the physiological action of pyrophosphoric acid, especially as a cardiac poison.—Professor Kronecker (of Leipzig) said that he believed that the substances referred to were really muscular poisons of the heart; that he saw no reason for doubting that they acted on the muscular substance of the heart; and that the experiments might be explained by supposing that the muscular substance of the auricle presented a different character from the muscular substance of the ventricle; that they did not act as poisons to the voluntary muscles; but that they acted as direct poisons to the muscles of the heart.

The Nervous Apparatus of the Lung.—Dr. W. Stirling pointed out that numerous nerve-cells were found in various organs of the body, and that the lung was no exception in this respect. There were numerous nerves entering the lung and accompanying the bronchi and blood-vessels. These nerves were derived from the pneumogastric and sympathetic nerves, which nerves accompanied the blood-vessels. In the course of these nerves numerous small masses of nervous matter, constituting ganglia, quite visible to the naked eye, were intercalated. These ganglia were most numerous around the bronchi at the base of the lung, and could easily be isolated by means of a dissecting microscope. The probable destiny of each of the two sorts of nerve-fibres—white and grey—found in the ganglia, was indicated; the former supplying the bronchial mucous membrane and the bronchial muscles, while the latter probably presided over the muscular fibres of the blood-vessels, and so, controlling the calibre of the vessels, regulated the amount of blood passing

through them.—Professor Gairdner pointed out that there were certain circumstances in which parts of the lungs were exposed to undue strain and dilatation, while the supply of air to those parts appeared from stethoscopic examination to be regulated so as to protect them, and asked whether Dr. Stirling could explain how this protection was afforded.—Dr. Stirling informed Professor Gairdner that the question of the supply of air to the different air-vessels was an extremely difficult one, but he thought that probably the regulating centre lay higher up than the medulla, and that a limited portion of that centre might affect only a limited portion of the nerve-cells lower down, because it was well known that if a single fibre were stimulated, the structures in which that fibre terminated would be the only ones acted upon.—Dr. McKendrick was of opinion that the ganglion centres discovered by Dr. Stirling might act as local centres for structures higher up.

The Brain of the Canidæ.—Mr. R. Garner read a paper on the size, etc., of the brain of the Canidæ. From measurements of brain-capacity, and from casts taken from the interior of the skulls of numerous dogs, the author drew the conclusion that the size of the brain did not correspond very closely with the size of the animal. He was disposed to argue the descent of the domestic dog (he did not treat of the origin of the dog primitive) from one or more dogs, as no dog had as large a brain as the wolf, nor one so small as the jackal, from both of which the descent of the dog had often been inferred. The size of the brain in the dog varied very little in the different sized animals, that of a Newfoundland dog being very little larger than that of a terrier; and the intelligence of the animal did not increase with the size of the dog, though in specific species there was an increase of intelligence in proportion to the increased size of the brain. He could not connect the powers of dogs with any peculiarity of brain organisation, but he found that in dogs with fine scents the front brain was elongated or enlarged.—Professor Macalister (of Dublin) desired to give the results of his examination of the brain of the celebrated greyhound 'Master M'Grath,' and stated that, after examining the brains of a great many other greyhounds, he was surprised to find that 'Master M'Grath's' brain was a good deal heavier than that of any of the others, and that it was not only larger, but that the convolutions were much more complex. He had also found that in complexity of convolutions the brains of dogs varied as much as those of human beings. He did not agree with Mr. Garner that the proportional weight of the brain of the wolf was greater than that of the dog, the result of his investigations in this respect being to place the brain of the pointer first, those of the mastiff and setter next, while that of the wolf took the third place. The greyhound had a very small brain in comparison with its size. He had found in the case of 'Master M'Grath' that the heart was exactly double the weight of that of an ordinary greyhound, and he would suggest whether it might not be that the great speed of that animal was due to this fact, it being a curious coincidence that the famous horse 'Eclipse' had a heart two-thirds heavier than that of any horse of his own size.—Professor Allen Thomson put it that, in the case of the size of the heart, there might be a way of looking at the question that was exactly the inverse of that which it was regarded by Mr. Macalister. He should be rather inclined to think that the large heart

was the result of the running, and not that the speed was produced by the size of that organ.—Mr. Garner pointed out that, of course, the question of structure must be considered, as well as that of size, otherwise the elephant and the whale might be supposed to have greater brain-power than man.

Physiological Action of Chromium.—Mr. Priestley offered some observations on the physiological action of chromium, stating as the results of experiments performed on rabbits, guinea-pigs, and frogs, that the action of chromium was twofold; first, it induced irritation of the alimentary mucous membrane, which was evidently congestion and ecchymosis; and secondly, it acted directly on the great nerve-centres, causing convulsions, paralysis, vomiting, a fall of blood-pressure, and a sudden and temporary stoppage of the heart in dilatation. It was not specially a poison of muscle or nerve trunks.—Professor Gamgee remarked that physiological investigation bore out the judgment of chemists, as they had said that chromium was unlike vanadium, while the physiologist had ascertained and asserted the same fact.

The Effect of Esmarch's Apparatus on the Circulation.—Professor Gamgee read a paper on the changes of circulation which are observed when blood is expelled from the limbs by Esmarch's method. The author stated that experiments carefully conducted on Esmarch's method with healthy students had produced the following results. When the blood was expelled from one leg the heart beat more rapidly, but only for a short time, and the same result followed the application of the bandage to the second leg. When the heart began to beat at its usual rate, the tourniquets were loosened, and in an instant the limbs, previously blanched, became suffused with a blush, while sensibility therein became more and more blunted, and the heart bounded off at an exceedingly rapid rate, to return, however, to its normal beat almost immediately. In applying the bandage, the blood in the veins was first expelled, then that in the arteries, and next there was an expulsion also of the lymph. He was of opinion that compressing the limb would send more blood into the veins than into the arteries, and as the lymph would go to swell the venous pressure, the venous blood *plus* the lymph would be greater in amount than the blood sent into the arteries. But the valves in the veins would prevent the increase of pressure in all parts of the system. It had been suggested that the increase of heart-beat, when the bandage was applied, was intimately connected with the diminution of the normal difference between arterial and venous pressure; that, if the right side of the heart were subjected to greater pressure, that would cause an increase of the cardiac contractions. These certainly were facts making it likely that an increase of pressure on the right of the heart tended to quicken the heart-beats; and the quick beats on the removal of the bandage were no doubt the result of the removal of the arterial pressure.—Professor Kronecker pointed out that they must consider the influence of the altered chemical composition of the blood on the heart-beats by reason of the addition of the products of the waste of tissue included in the lymph. He did not see that it should be concluded, from the effect of the sudden change of pressure on the sensibility of the skin, that the circulatory apparatus was affected in the same way, for the observations of Tscheriew showed that an increase in the blood-pressure seemed to increase the rate of cardiac pulsations.

REPORTS OF FOREIGN SOCIETIES.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The following are the principal papers which were read at the recent meeting at Clermont Ferrand, classified under their different headings.

ANATOMY AND PHYSIOLOGY.

On some points in the Anatomy and Physiology of the Sclerotic.—M. Gayet treated in the first instance of the fibrillary substance which presents itself in the form of layers meeting each other at very acute angles, so that the sclerotic is constituted by a thick felting and not by layers of fibres in parallel directions. When we divide these fibres, of which the layers take every possible direction, we see that they have a great tendency to curl up, and consequently to become shortened. There are two orders of vessels, those which traverse that organ to penetrate into the deep portions of the eye, and the nourishing vessels of the membrane. The first pass through the sclerotic in a kind of sheath lined with stellate cells, which seem to come from the lamina fusca. The others have no sheath. The fibres of the sclerotic insert themselves under their walls, and thus keep the lumen of the canal open.

On the Effects of the Excitement of the Sensory Nerves on the Heart, the Respiration, and the Circulation.—M. Franck, in giving a general view of his cases, adopted as a formula the thought of M. Claude Bernard, 'Stoppage of the heart, or syncope, may occur under the influence of an intensely painful excitement, of whatsoever nature it may be.' Under the influence of a painful excitement, the heart stops, and that stoppage is more or less considerable, according to the intensity of the impression, the sensibility of the animal, etc. The suppression of pain by anæsthesia brings on the suppression of the cardiac reaction, because the instrument of the cardiac manifestation is wanting, the pneumogastric nerves being paralysed.

MEDICINE.

On some little-known Changes in the Mucous Membrane of the Stomach.—M. Gallard observed two cases of hæmatemesis which could not be attributed to any change in the stomach, but might be referred to the rupture of small aneurismal tumours, described by M. Liouville under the name of miliary aneurisms. In the first case, the necropsy revealed a minute ulceration attached to an arteriole; it was a miliary aneurism. In the same case the same colouring was found in other points, due to the same cause. M. Gallard showed also a case of diabetic ulcer of the stomach in an alcoholic patient, and drew attention to the fact that the name of ulcer of the stomach is given to a large number of different lesions.

Neuralgic and Visceral Neuroses in Cerebro-Spinal Diseases.—A paper on this subject was read by M. Teissier, sen., of Lyons. Visceral disturbances are met with equally in the first period of general paralysis, and of sclerosis of the anterior columns. M. Teissier had, indeed, observed them in a case of angina pectoris, which for several months masked the commencement of diffuse encephalitis; in gastric crises with hæmatemesis, also at the initial period of general paralysis, in a case of violent and paroxysmal enteralgia in a lady who subsequently became

paralytic; in two cases of convulsive bronchitis, completely simulating whooping cough and lasting several months in ataxic patients; in several cases of extreme frequency and irregularity of the pulse, without any appreciable lesions of the heart; in an unusual case of neurosis of the heart, of which the attacks were later on replaced by epileptiform crises.

Accidents following the Operation for Empyema.—M. Leudet, of Rouen, related the case of a patient who, after an operation for empyema, either by the friction of a *sonde-à-demeure*, or by the washing out of the pleura, felt numbness and pain in the right hand, whilst the pleural fistula was situated on the right, with passing aphasia and visual troubles. These accidents were, according to the author, of a reflex nature, and sprang from the irritation of the pleura.

Characters of the Pulse in Painter's Colic.—M. Teissier, sen., of Lyons, said that the pulse in this disorder is slow and vibrating, and its trace shows a short ascensional line, slightly inclined at the top with two rebounds, of which the second is more accentuated than the first.

Phimosis in its Relations with Diabetes Mellitus.—According to M. Bourgade, this phimosis, already pointed out, is due to irritation caused by the sugar in the urine. The interesting point of this communication is the author's recommendation not to operate on phimosis due to this cause, and the precaution he advises not to attempt the operation until after having analysed the urine.

Otoscopy applied to the Diagnosis of Deafness.—In a paper on this subject, M. Philipeaux, of Lyons, said that if a patient do not hear the tick of a watch placed on the mastoid apophyses or the temporal bone, we must not always make up our minds to the presence of an incurable deafness, owing to a paralysis of the acoustic nerve. The presence of a plug of cerumen compressing the middle, and even the internal ear, by the chain of ossicles, may produce this phenomenon, which disappears if the plug be removed.

The Relation between Pleurisy and Hydatid Cysts of the Liver.—M. H. Petit described three cases, in which it was demonstrated that an intercurrent pleurisy had the clearest effect on the development of pre-existent hydatid cysts.

Hordeaceous Bezoards.—A man came to consult M. Prunières, of Marvejols, for a cancrroid of the lips, on which he operated successfully. Some time afterwards, there were diarrhoea, colic, and abdominal pains, which gave rise to apprehensions of an intestinal generalisation of the disorder. Suddenly, however, the patient evacuated a large number of round, hard, chestnut-like bodies. Whence came these concretions, since the patient did not eat chestnuts? Specimens were sent to M. Robin, who replied that they were due to an accumulation of husks of oats or perhaps of barley. At the same time, M. Prunières learned of his patient that a medical man had recommended him to eat unbolted barley meal, and that he took it from time to time.

On Diabetic Ulcers and Fistula.—M. Cornillon, of Vichy, recorded three cases in which fistulae, inveterate remains of abscesses which had supervened in diabetic patients, extensive ulcers lasting for an indefinite time, disappeared in a few days under the influence of alkaline treatment. The diabetes had been improved, and the improvement had immediately exercised an influence of the local affections, whether ulcers or fistulae.

On the History of Exophthalmic Goitre.—According to M. Gagnon, of Clermont, exophthalmic goitre may supervene before the age of puberty. The author also quoted a case in which the relations between cholera and exophthalmic goitre were demonstrated in the clearest manner.

SURGERY.

On Resection of the Upper Maxillary Bone.—M. Letiévant recommended a modification in this operation, consisting in the preservation of the suborbital nerve, which keeps up the mobility of the facial mask, and the rapid and energetic reaction of the muscles, under the influence of the will and of electricity.

On the Successful Results of Surgical Treatment at Home.—M. Baraduc gave the results of ten years' surgical practice in a very large coal-mining establishment. The most serious wounds scarcely ever had unfortunate results, which the writer attributed in the first instance to the goodness of the Auvergnat race, and specially to treatment at home. He therefore very strongly opposed the establishment of an hospital.

Amputation performed on a Patient suffering from Albuminuria.—M. Verneuil laid it down that no operation should be attempted on patients suffering from diabetes or albuminuria. Any injury rapidly carries off patients under these conditions. There are, however, exceptions to this rule, of which M. Terrillon quoted a remarkable one. The case was that of a man, aged twenty-nine, who, being drunk, fell down and broke his fore-arm, and at the same time wounded himself so as the wound communicated with the seat of the fracture. Notwithstanding the most methodical dressing, a diffused phlegmon supervened, accompanied by *delirium tremens*. The phlegmon made such progress that, notwithstanding the presence of an enormous quantity of albumen in the urine, M. Terrillon decided on performing amputation of the arm, which was followed by immediate improvement, rapid cicatrization, and complete disappearance of the albumen.

On the Treatment of Epulis.—M. Bercheron recommended the employment of caustics, especially of Vienna paste, which had been more successful in his hands than the bistoury and the linear écraseur.

On the Treatment of Uterine Inversion by the Elastic Ligature.—In a case of uterine inversion in which he had tried reduction ineffectually by all the means usually employed, M. Arlès drew out the inverted uterus and surrounded it by a moderately tight India-rubber tube. The results were very simple, and the tumour came away in a fortnight. M. Arlès affirmed that the elastic ligature is superior to all the methods hitherto employed.

On an Undescribed Variety of Epithelioma.—M. Paul Réclus said that the upper jaw may be the seat of rapidly progressing epithelioma, characterised by a spacious cavity and lined with exuberant granulations. It is probable that these perforating epitheliomata originate in the cysts often attached to the roots of the teeth. These cysts, as well as the ordinary epitheliomata of the jaws take their rise in the epithelial *débris* which are the vestiges of the budding of the cords of the first and second teeth.

On Certain Forms of Coup de Fouet.—There are a mild form and an acute form of *coup de fouet*. The latter is most generally met with in varicose patients. M. Verneuil cited several examples, of which one was followed by purulent infection and the death of the

patient. The opinion of J. L. Petit on the rupture of the small femoro-calcaneal muscle has never been confirmed by necropsy. M. Verneuil admitted the opinion of the elder Sédillot, who believed in a muscular rupture. But M. Verneuil attributed the serious forms of *coup de fouet* to the rupture of the large varicose veins, which traverse the muscles of the calf. At the moment an effort is made, they break, whence sudden pain, considerable ecchymosis, phlebitis, and all the accidents which may arise from it. M. Verneuil recommended the greatest precautions when the *coup de fouet* occurs in a varicose patient; repose, immobility during several days, until phlebitis is averted or cured, if it shows itself.

Tuberculous Ulcers of the Roof of the Mouth, Gums, and Lips.—M. Le Dentu stated that tuberculous ulcers of the lips had not hitherto been noted. They do not differ in appearance from tuberculous ulcers of the tongue.

On Traumatic Oliguria.—A paper by M. Nepveu referred to two cases of consecutive oliguria; one from a blow in the lumbar region, the other from a penetrating wound of the small pelvis and the abdomen.

PSYCHOLOGY.

Case of Double Consciousness.—M. Azam of Bourdeaux related the case of a young girl who exhibited very strange phenomena. After the slightest vexation, the slightest emotion, her head fell on her breast, and she fell into a light slumber. At the end of a few minutes she woke very lively, attended to her daily occupations, and in two or three hours again bowed down her head to go to sleep. When she awoke she had no memory of what had occurred in the interval of the two slumbers. The amnesia was complete. This girl became pregnant; in one of her conditions, she knew it, spoke of it, and named the father of the child; in the other she was ignorant of all these details, even to the pregnancy itself. The other details of this case showed very varied hysterical phenomena, convulsions, paralyses, hæmorrhages, red spots on certain parts of the body. The latter phenomena involuntarily invite comparison between this fact and a recent celebrated case of so-called stigmatisms.

ENDEMICS AND EPIDEMICS.

The Etiology of Goitre in the Puy-de-Dome.—The predisposing causes of goitre, according to M. Rivet, are living in a valley or a humid plain, dwelling in rooms in which the air is charged with organic matter or carbonic acid, excessive sweating, overwork, insufficient and bad nourishment. Acute goitre, if uncared for, may become a nidus of endemic goitre, and give rise to constitutional and hereditary disease. M. Rivet ascribed an important part in the production of goitre to the great atmospheric currents coming from the western mountains. The author seemed inclined to attribute the goitre to a rheumatic affection of the vaso-motor system of the thyroid gland. He made no distinction between endemic and acute goitre, and as to its production only recognised a single cause; but he considered the disease as the result of a concurrence of various circumstances.

On Cholera in the Centre of France.—M. Mignot, who had observed more than seventy-five cases of cholera nostras, believed it to be incontestable that in certain cases, as in Asiatic cholera, it may take on an epidemic form.

SYPHILOGRAPHY.

On Syphilis by Conception.—M. Diday thus called syphilis transmitted from the foetus to the mother. This transmission has been denied, and it has been maintained that the infection came from the husband, and that the existence of an initial chancre in the woman had been misunderstood. M. Diday reported twenty examples of women having been infected with syphilis by the foetus, and in whom no traces of chancre existed. A man may then infect a woman both as husband and as father.

FORENSIC MEDICINE.

On the Medico-Legal Aspects of Deglutition in New-Born Infants.—M. Houzé de l'Aulnoit related the following case. A new-born infant, immediately after birth, and before it breathed, was thrown into liquid in the common sewers. At the necropsy, it was found that the child had swallowed, though docimasia indicated that it had not breathed. Could it be said that it had lived?

On Pulmonary Docimasia.—M. Laennec, of Nantes, stated that if a portion of lung which has not breathed be triturated, this manœuvre drives out the gas it contains; if the lung then be thrown into water, it will inevitably sink to the bottom of the vessel. But if the lung have breathed, notwithstanding a lengthened and strong trituration, the same portion of lung will swim. M. Laennec extolled this method in cases where the putrefaction of the lung would seem to make all researches unavailing.

ETHERISATION.

Etherisation in Young Children.—Generally considered as inoffensive, etherisation in young children, as performed by M. Tripier, of Lyons, has given rise to grave accidents, without, however, causing the death of any child. In children from five to eight years old, he has observed a sudden arrest of the respiration, with persistence of the cardiac movements. There was at the same time an abundant expectoration of thready mucosities proceeding from the bronchi.

OPHTHALMOLOGY.

On a Modification of Von Graefé's Method for the Operation of Cataract.—M. Galewski no longer performs sclerotic puncture and counter puncture; he localises the entire wound in the limits of the cornea; thus he leaves the linear wound on one side to replace it by a lower flap in the place of the upper flap. He attributed to this lower excision a great part in the successes which he has obtained, which are ten per cent.; since, out of sixty-seven operations performed by him in private practice, he had not recorded one single failure.

On the Treatment of Detachment of the Retina.—Contrary to Von Graefé's opinion, M. Galewski believed in the cure of this accident, which may be caused either by choroidal inflammations, or by the destruction of the retinal vessels, occasioned by a serous transudation. In the first case, antiphlogistic treatment brings on favourable results. In the second case it is necessary to withdraw a certain quantity of liquid as promptly as possible; and for this purpose, the writer had a small syringe constructed on the model of Dieulafoy's syringe, with which he can remove the serous liquid effused into the eye without issue of the vitreous body.

On Drainage of the Eye.—To remedy excessive secretions of liquid into the eye, M. Wecker proposed a drainage, which he performed by means of the

metallic threads introduced by him across the membranes of the eye, and which he leaves *in situ* during the time necessary.

On Progressive Myopia in Women.—M. Chibret stated that progressive myopia is very serious in women. It is necessary to order the use of spectacles appropriate to the various forms of myopia.

THERAPEUTICS.

The Employment of Carbolate of Soda in Nervous Affections of the Respiratory Passages.—M. Pernot stated that he had employed this agent successfully in spasmodic affections of the respiratory passages, such as whooping cough and influenza.

On the Treatment of Chronic Parenchymatous Metritis by Ignipuncture.—M. Courty, of Montpellier, had obtained excellent results in this disease, long thought incurable, by deep cauterisation of the neck of the uterus with small spherical cauteries terminating in a point of from one to three centimètres long.

On the Treatment of Coxalgia.—M. Ollier, of Lyons, passed in review the principal means recommended against coxalgia, viz., continuous extension; frequent movements producing the rupture of the attachments, and the resection of the head of the femur. Neither of these methods obtained M. Ollier's approval. He considered sudden extension and immobilisation as the two chief indications to be fulfilled in the majority of cases, associating with this treatment sea-air, and forbidding any thermal treatment.

Deformities of the Sole of the Foot, especially in Children, in Atrophic and Paralytic Affections of the Leg.—M. Onimus showed a cork sole, manufactured by M. Collin, intended to remedy these deformities.

On Paralysis of the Muscles of the Arm cured by Continuous Currents.—M. Dagrève related a case of paralysis consecutive on arthritis of the elbow, lasting two years, and which disappeared after three applications of electricity.

On the Caustic Properties of Bromide of Potassium and its use as an External Application.—In consequence of experiments on rabbits in which M. Peyraud of Libourne saw that the skin which had been affected by solution of bromide of potassium dried up at the end of some days, he thought that advantage might be taken of that escharotic property to destroy certain malignant and other tumours. In fact, in twenty-eight days he had destroyed to the pedicle, by daily applications of bromide of potassium, a canceroid fungous mass which had invaded two-thirds of the skin. M. Besnier cured, some time after, by the same means, a hypertrophic lichen of the leg, and avoided the amputation of the limb.

APPARATUS AND INSTRUMENTS.

New Pneumograph.—MM. Colrat and Rabatils's pneumograph differs from those already in use, inasmuch as it is able to indicate in an independent manner the movements of the right half and the left half of the thorax. Nevertheless, the inventors candidly stated that the applications of their study of unilateral diseases of the chest only yields incomplete results.

New Æsthesiometer with Isolating Points.—The terminal points of the new æsthesiometer of M. Manouvriez, jun., of Valenciennes, are made in ivory, and are a safeguard against the error produced by the conductivity of the old apparatus, which therefore easily place themselves in an equilibrium of temperature with the body.

New Apparatus for Fractures of the Lower Limbs.—According to the inventor, M. Fabrequettes, of Saint-Etienne, this apparatus, a modification of Bonnet's trough, offers the following advantages. Counter-extension is safe and efficacious. The reduction is gradual, and is performed without sudden concussions; coaptation is kept up in a certain manner; finally, the dressings are in no way interfered with, and the patient can sit up in bed.

HYGIENE.

On the Mortality of Young Children.—M. Dubert said that this must be attributed in some part to the ignorance of mothers, who very soon begin to give solid food to their suckling children. Some elementary notions of hygiene should be given to these ignorant mothers, and M. Dubert suggested that a short appendix, containing indispensable precepts on this subject, should be appended to prayer-books, missals, and religious books in general.

ACADEMY OF MEDICINE IN PARIS.

August 29. *Manifestations of Rheumatism or Gout in Calculous Patients after Operation.*—M. Courty read a memoir on this subject, in which he stated that besides the general accidents of all operations, and, besides the special accidents which depend on stone, purulent cystitis, urethritis, nephritis, albuminuria, uræmia, etc., diathetic accidents, attacks of gout or rheumatism, affections congeneric with gravel may yet be manifested as the consequence of operations for stone, which seem to be aroused or brought on, if not produced, by the concussion, the commotion or the shock, as it may be termed, of the operation itself, either by cutting or by lithotripsy.

August 12. *On a New Method for the Abortive Treatment of Anthrax.*—M. Jules Guérin read a note on this subject. Starting from the idea that the accidents constituting the accidental malignity of the anthrax are the result of the absorption of septic liquids contained in the form of this tumour, the indication consists in anticipating and neutralising the septic decomposition of the cores, and in stopping the decomposed matter on its way. The best means of realising this object is the application of a blister on the most inflamed zone of the anthrax. The blister should be large, and cut in the centre. If this proceeding be adopted at the first stage of the anthrax, this application has the effect of stopping accidents, of calming pain, of changing the consistence of the tumour, and of rendering it of a mild character and of easy enucleation, even without the help of the bistoury.

August 19. *On Heredity in the Production of Cerebral Hæmorrhage.*—M. Dieulafoy reported several examples which he had recently had the opportunity of observing, and in which heredity was evident. This heredity is as pronounced as that of pulmonary phthisis, for instance. Cerebral hæmorrhage appears in general at an advanced age; nevertheless, it sometimes freely strikes down many members of the same family at various periods of life; it is not even rare that in the same line a younger generation is attacked before an older one.

ACADEMY OF SCIENCES IN PARIS.

August 7. *Glycæmia.*—M. Claude Bernard demonstrated in a note, that glycæmia is the result of

a physiological function, that it takes its rise in the organism itself and not in alimentation. He also presented the comparative results which have been furnished by the examination of the blood taken from different parts of the body. In the general venous system the proportion of sugar is variable, but always inferior to that of the arterial blood. In the line of the arterial system, the blood contains a sensibly identical portion of sugar. M. Thénard pointed out that the results obtained in analysis of this kind are influenced by the operative method, according as the peculiar force, designated by M. Chevreuil under the name of capillary affinity, is destroyed or not. He has succeeded in neutralising that affinity by fifteen degrees of cold.

Bacteria.—M. Pasteur replied to Dr. Bastian's objections to his theory of fermentations. He maintains that boiled urine rendered alkaline by solid potash, no longer produces bacteria; that fresh urine, as it leaves the bladder, and saturated in the same way without preliminary boiling is likewise sterile.

The Dura Mater.—M. Bochefontaine presented a note on some peculiarities in the reflex movements brought on by mechanical excitation of the cranial dura mater. It is possible not only to provoke movements caused by pain, but also movements limited to the muscles of the face on the side corresponding to the portion excited. It appears as if these movements are due to the direct transmission of the excitement on the same side of the spinal marrow.

August 14. *Glycæmia*.—After having demonstrated that glycæmia cannot proceed from alimentation. M. Claude Bernard showed that it is connected with the glycogenetic function of the liver. He laid down the following positions. 1. The blood of the subhepatic veins is more saccharine than the arterial blood and the blood of the vena portæ; 2. The blood of the inferior vena cava becomes suddenly rich in sugar, before entering into the heart, at the level where the subhepatic veins pour out their contents.

Trephining.—M. Ollier read a memoir on trephining of the bones in the various forms of osteomyelitis. This operation should be reserved for cases in which the inflammatory nature of the lesion cannot be doubted. In the organic lesions of the bones, trephining may always act as an operation for *débridement*, but it would open the way to the most serious accidents; amputation of the limb, or ablation of the bone, are the only rational operations.

Athrepsia.—MM. J. Parrot and Albert Robin presented a memoir on the changes of the urine in the athrepsia of new-born children. The urine in athrepsia is always coloured from pale lemon colour to the deepest yellow, always odoriferous, frothy, flat or aromatic, always diminished in quantity, its density varies from 1009 to 1012.5. The reaction is always acid; the urea varies from 3.63 grammes per litre, and 1.22 grammes per kilogramme, weight 16.19 and 5.89 grammes. Uric acid, urochrome, and indigose are often increased, but the albumen, variable as to the epoch of its appearance, is never wanting in any patient; sugar is frequent. The chlorides are on an average from 3.09 grammes per litre, and from 1.28 grammes per kilogramme, phosphoric acid from 0.95 to 2.24 grammes. The approach of death is announced by the accentuation of all these specialities, and above all by the lowering of the quantity of

consecutive deposits of urate of soda, the augmentation of the uric acid, the albumen, etc. Diarrhoea is announced by a diminution in the quantity of the urine, and the appearance or increase of indigose. Anxiety, agitation, cries of anguish, are often in proportion to the diminution of the quantity, the augmentation of the uric acid, and the glycosuria. The diminution of the acidity, the somewhat elevated amount of the chlorides, and of the phosphoric acid, the small quantity of urea, and the light colour, announce that the child is still slightly nourished, and may be reckoned amongst the number of favourable symptoms if they are accompanied by a diminution of the albumen. Syndromata of the same order coincide with the rise of the sudden lowering of the temperature, great losses of weight, certain complications, etc.—MM. Polli and Pietra Santa claimed the priority of the antiseptic method set forth by M. Larrey, in the name of Dr. Minich.

REVIEWS.

A History of Asiatic Cholera. By C. MACNAMARA, F.C.U., Surgeon to the Westminster Hospital. London: 1876.

Mr. Macnamara's object in writing this book has been to convey to educated Englishmen important, and, so far as the subject admits of it, exact information on a matter which affects the well being of a vast number of their fellow creatures. We could wish that 'educated Englishmen' out of the medical profession could be induced to read what Mr. Macnamara has so well written; but we greatly doubt whether, until another cholera invasion of this country is imminent, many non-medical readers will be found to benefit by our author's labours. So long as cholera is at a distance from our shores, and confines its ravages to natives of other countries, or even to our own countrymen in India, the general public will leave the study of the history of cholera, which so much concerns us all, to professional students. When a steam-boiler in a man-of-war on our own coasts bursts and destroys and injures forty or fifty men, public sympathy is immediately and most justly awakened, and neither time, money, nor labour are grudged to trace out the cause of the accident with a view to prevention in the future. But an epidemic of cholera, starting from its endemic area in Lower Bengal, may sweep over India and destroy, as Mr. Macnamara says, 'on each occasion millions of human beings, many of them in the prime of life,' without exciting more notice than a few paragraphs in the daily journals.

In the work before us, Mr. Macnamara gives us clearly the history of the six great epidemic outbursts of cholera, which since 1819 have spread over the world. 'There is no great difficulty,' says our author, 'in tracing out the progress of the earlier epidemics of cholera over Europe and America, but of late years, in consequence of the more rapid communication established between India, Persia, and Russia, cholera has shown a tendency to localise itself beyond the confines of Hindostan, and so it has become impossible to follow each outburst of the disease from Western Europe back to its starting-point in Bengal. But this present difficulty makes it all the more important for us to study the earlier history of cholera, and by means of the knowledge thus ac-

quired, to examine its characteristic features where it has appeared under more complicated circumstances.'

The first chapter is devoted to a definition of cholera, and to the history of communication between India and Europe. Mr. Macnamara's definition of cholera is, in its main features, the same as that now accepted by the best authorities in Europe, and so ably developed by Simon—viz., that it is a disease which is capable of being communicated to persons in sound health, through the *dejecta* of patients suffering from this malady, and that drinking water, as first clearly shown by Snow, is the main channel by which the poison finds its way into the system, the *dejecta* of affected persons percolating through the soil in ill-constructed drains into wells or rivers from which drinking water is supplied. The propagation of the disease by various articles of diet in like manner contaminated, or by atmospheric impurity from air charged with exhalations from the 'choleraic forces,' from carrying the bodies of those who have died of the disease for burial, or washing or wearing linen soiled with the discharges of cholera patients. The important fact that the organic poison of cholera in a dried condition may retain its dangerous properties for a considerable time, and thus the disease be carried from one country to another, is also admitted. The manner in which cholera has thus been carried in the clothes of emigrants from infected localities in the centre of Europe, causing an outburst of the disease in a crowded ship in mid ocean, or, when opened after arrival, on the continent of America, as proved by the investigations of Dr. Woodworth, Marine Hospital Surgeon in New York, may be taken in illustration of this part of Mr. Macnamara's account of the way the disease is sometimes propagated. In fact the lesson inculcated, and as he believes proved, in this important work is, that cholera is disseminated from its endemic area by means of human intercourse, man carrying it with him from congregation to congregation.

Mr. Macnamara then gives in considerable detail the early trade routes between India and Europe. In the course of his observations on this point, our author goes a little out of his way to introduce some remarks drawn from his professional intercourse with the mothers and wives of the native inhabitants of Calcutta, on the perversion and moral corruption of the rising male generation of native society, arising from the rapid diffusion of European ideas, laws, and literature among them. We do not doubt that the lives of a not inconsiderable number of the educated native youths (Young Bengal) of Calcutta are very unlovely, not only in the eyes of those whose lives are spent in the zenana, but to all beholders. But surely our author is not simple enough to believe that Hindoo beliefs, ideas, and practises, still held sacred in zenanas, can stand before the culture, crude and imperfect as that may be, to which the minds of 'Young Bengal' are subjected in the schools and colleges established by the conquering race. Mr. Gladstone has well shown that no race with any pretension to civilisation has ever passed directly from one belief to another without passing through an intermediate stage—one of negation of all beliefs. This is the stage of transition through which the young men in Calcutta are now passing; it is, as we have said, most unlovely, and, we can well understand, very incomprehensible and abominable in the eyes of the Aryan wives and mothers, whose minds are little if at all touched by

contact with the new world of thought, life, and manners introduced by Europeans. While it is a melancholy fact that our vices are more easily imitated than our virtues by 'Young Bengal,' is it so certain that the morality inculcated in the zenana was so pure and elevated that we need, like Mr. Macnamara, think, as he appears to do, that the diffusion of European ideas, laws, religion, and morality is too great a price to pay for the loss of it, merely because the first effect of their introduction is not in some respects pleasing? Others as well as Mr. Macnamara have had as ample means of seeing zenana life, and its effects and influence on the minds of the young, without seeing cause to regret that it is giving way to a more robust and healthy training. For ages before the introduction of European ideas into the education of both sexes in India, zenana education had its own way; was the outcome such as to excite admiration or cause us to regret that it is passing away? We offer the rising generation of India something more than 'the heartless system of moral philosophy and ethics,' which Mr. Macnamara says 'is all we give in exchange' for the 'sacred obligations' of their own religion; we offer them a purer faith and a higher system of morals, and our hope and belief is that, the stage of transition passed, to which we have adverted, thousands will embrace both, and enter on a higher life and practise a purer morality than ever was taught in zenanas.

For the clear history of the various epidemics we must refer to the work itself, which is a store-house of important facts on all relating to the progress and geographical distribution of the disease. We are particularly pleased to see that the author devotes a chapter to the history of cholera prior to the year 1817. In this chapter, following the investigations of Dr. John Macpherson, the vulgar notion that this disease took its origin in that year is once more and effectually exploded.

There is an interesting chapter on the bearing of meteorological influences upon the spread of cholera. Mr. Macnamara thus expresses himself on the influence of the south-west monsoon, so much insisted on by those who advocate the views of Dr. Brydon. 'It seems to me that these facts are best explained as follows: when the south-west monsoon sets in over Bengal, the river Ganges becomes the great high road of traffic between the home of endemic cholera and the north-west provinces. After the cold season crops have been gathered in, and the monsoon has fairly begun to blow over Bengal, large fleets of country boats start on their journey from Calcutta, Dacca, and other emporiums of trade, for Patna, Benares, Allahabad, Mirzapore, and Cawnpore, which latter place they reach about August. A few of these boats sail up the Jumna as far as Agra, and even Delhi. The south-west monsoon, therefore, would appear to be the indirect cause of the dissemination of cholera over the country, in that it brings with it moisture, a necessary element for the development of the disease, but more especially because it is before this wind that the large fleets of country boats move up the Ganges, conveying men and goods from the home of endemic cholera to be disseminated over the upper provinces; a repetition of the old story, cholera progressing with naan along the great high roads upon which he travels, spreading no faster than he moves, and being generated in wet and hot weather.'

This valuable work concludes with an appendix

describing the characteristic features of Asiatic cholera, the term used by Mr. Macnamara throughout, and a description of the precautions best suited in the present state of knowledge to prevent its spread.
W. C. MACLEAN, M.D.

Traité Pratique des Maladies du Larynx, précédé d'un Traité complet de Laryngoscope. Par le Dr. CH. FAUVEL. Avec 144 figures dans le texte et 20 planches dont 7 en chromolithographie. Paris : Delahaye. 1876.

Practical Treatise on Diseases of the Larynx, preceded by a complete Treatise on the Laryngoscope. By Dr. CHARLES FAUVEL. With 144 woodcuts, seven chromo-lithographs, and thirteen other plates. Paris : 1876.

This important work of 900 pages is only the first part of the complete treatise. It deals with the laryngoscope and its accessory apparatus, with laryngoscopic surgery, with laryngeal polypi and cancer of the larynx. The second part, which is promised, will contain catarrhs, syphilis, phthisis, and paralysis, and will conclude with an article on rhinoscopy and diseases of the posterior nares. If all the subjects be treated with the amplitude which has been permitted with regard to benign and malignant growths, this work bids fair to be one of unusual dimensions. On analysing the volume before us, we find that 130 pages are taken up with a description of polyps and the instruments necessary to remove them, and that 400 pages are occupied with the clinical histories of 300 cases, which the author met with between the years 1862 and 1875. Rather more than 60 pages are devoted to the investigation of cancer, and 120 pages to the detailed description of thirty-seven cases of primary cancer of the larynx, which have come under the author's notice since 1862. The rest of the work consists of an excellent description of the laryngoscope, of the various kinds of illumination, of the art of laryngoscopy, and of the various instruments for applying remedies to the larynx.

It will be seen then that the work is, in fact, an elaborate monograph on growths in the larynx, and that the greater part is occupied with the description of those benign neoplasms which it is the delight of the laryngoscopist to eradicate. Dr. Fauvel now establishes by undoubted proofs that reputation for skill, which he has long enjoyed; for it appears that, out of 300 cases that have come under his notice, 233 submitted to operation, and of these there were 180 complete cures, forty-eight cases of marked improvement, and only five instances in which no benefit resulted. When it is remembered that, twenty years ago, a very large number of these patients would have died suffocated, and that many others would have undergone tracheotomy, it cannot be denied that the laryngoscope has furnished a most important means of defence against one class of 'ills that flesh is heir to.' We may perhaps congratulate the public, if not the laryngoscopists, in this country, that growths appear to be more common in France than in England or Germany. It is probable that, the moister climates of these last-named countries predisposing to catarrhs, the tendency of disease as regards the laryngeal mucous membrane may be more towards muco-purulent inflammations than to new formations.

To many readers, however, the section of the work devoted to cancer will prove the most interesting. Medical literature contains very few cases of primary

cancer of the larynx, and the detailed account of thirty-seven fresh cases cannot fail to be of considerable value. In nineteen cases the disease was encephaloid, sixteen were epitheliomatous, and two doubtful. Encephaloid cancer begins as a small, scarcely defined, and in no way characteristic tumour on one of the ventricular bands. In Dr. Fauvel's cases the left side of the larynx was far more frequently affected than the right, in both forms of cancer. Thus, in his thirty-seven cases, the disease commenced in twenty-six instances on the left side, and only seven times on the right side; in three the origin of the disease was uncertain, and in one case the epiglottis was the part attacked. Epithelioma is more easy to recognise in its early stages. It presents the appearance of a rapidly growing papilloma, which soon ulcerates and becomes covered with pus and mucus. As is usual in cancer, the greatest mortality took place in middle life and old age. Thus, thirty-seven patients were between forty and seventy, whilst there was only one patient who was under forty, and two over seventy. The greater disposition of the male sex to be affected with cancer of the larynx comes out very strongly in the author's cases, there being thirty-four men and only three women. Dr. Fauvel suggests that, in women afflicted with the cancerous diathesis, the uterus and mammae afford a more favourable nidus, and hence exercise a kind of protective influence on the larynx.

As regards the symptoms, the author thinks the voice, though often hoarse, is seldom completely extinguished, and this serves to distinguish it from laryngeal phthisis, in which disease, he says, the voice is generally altogether lost. Difficulty of respiration does not generally come on till long after hoarseness—a year often supervening between the inception of these symptoms. Dysphagia, which is rare in the early phases of primitive cancer of the larynx, generally supervenes towards the middle period of the disease, and increases till the patient is unable to swallow anything but liquids. Salivation was also a troublesome symptom in all Dr. Fauvel's cases. Pain, at first dull, but afterwards lancinating, and extending to the ears, orbit, and forehead, is almost always present. The characteristic odour, the disposition to repeated hæmorrhage and the glandular engorgement, complete the semeiology; but the author calls attention to the fact, that the cancerous complexion is often altogether absent—even in the case of patients who, having been tracheotomised, have survived for a considerable period. The author thinks that primitive cancer has little disposition to infect the system at large; but it must be borne in mind that he also admits that in a great many cases he could only obtain permission to examine the throat after death, and was not allowed to make a complete necropsy. It is sometimes difficult to distinguish syphilis and cancer; in the former disease, however, the malady is simply destructive, and there is an absence of any attempt at new formations. So difficult, however, is it to distinguish between the two diseases, that in all cases the author submits the patient to a course of antisyphilitic treatment.

Perhaps the most important and interesting portion of this article has reference to the termination of the disease and the influence of tracheotomy. The following are the author's statistics.

'In seven non-tracheotomised patients suffering from encephaloid disease, the mean duration of life was three years.

'In eight tracheotomised patients with encephaloid disease, the mean duration of life was three years and nine months.

'In six non-tracheotomised patients, with epithelioma, the mean duration of life was one year and eleven months.

'In seven tracheotomised patients with epithelioma, the mean duration of life was four years.'

It will be seen then that epithelioma of the larynx, if left to itself, terminates more quickly than encephaloid disease; and on the other hand that tracheotomy prolongs life for a greater period in epithelioma than in encephaloid disease. In the last named disease the prolongation of life presented a mean of nine months, whilst in epithelioma it was two years and a month. 'Tracheotomy thus always prolongs the patient's life.' As regards treatment, as already remarked, Dr. Fauvel treats all his cases with antisyphilitic remedies, on the possibility of the disease being venereal. Of course if the disease be so advanced that its nature is evident the author does not adopt the course indicated, but otherwise that is his plan. He uses mercurial frictions after Sigmund's plan, iodide of mercury, and in a few cases has employed mercury hypodermically. Whilst giving mercury he administers large doses of iodide of potassium, hot air baths, and Zittman's *tisane*. If this treatment do not arrest the disease, there is nothing to do but attend to the symptoms, give subcutaneous injections of opium, carbolic acid inhalations to diminish fetor, and atomised solutions of tannin in case of hæmorrhage. The author recommends tracheotomy as the grand surgical palliative, and speaks unfavourably of extirpation of the larynx. The article concludes with a thoughtful section on laryngeal cancer in relation to general cancer.

We have attempted to give a slight sketch of this most valuable work, which throughout is admirably illustrated. It is the most important book which has appeared since the invention of the laryngoscope, and reflects the greatest credit on the author and on the surgical literature of France.

Études Histologiques sur le Labyrinthe Membraneux, et plus spécialement sur le Limaçon chez les Reptiles et les Oiseaux. Par PAUL MEYER. Paris : 1876.

There are few researches in Histology which necessitate the exercise of so much patience, perseverance, and skill, as those required for the study of the delicate structures of the internal ear. This very delicacy of the soft tissues and the extreme hardness of the encasing bone, naturally present difficulties not to be met with in any other part of the whole body. It is therefore with a feeling of no common interest that we take up such a work as the one before us.

The author presents us with a careful *résumé* of the previous researches into the structure of the membranous labyrinth of birds and reptiles, and adds the results of his own personal labours. In considering this structure, as a whole, he follows the lead of Hasse, and divides it into *pars superior* and *pars inferior*; the former, comprising the semicircular canals and utricle, does not alter materially in proceeding up the animal scale; whereas the latter, including the sacculus and ductus cochleæ, makes regular progressive changes as the scale is traced from amphibians to reptiles, and then on to birds. This development of the *pars inferior* ne-

cessitates a very detailed account of its component parts in the several classes, especially as regards the cochlea.

In treating of the two points which, beyond all others, are of interest to the histologist, namely, the mode of termination of the nerves in the cochlea and in the acoustic areas of the vestibule and semicircular canals, M. Paul Meyer quotes the writings of Max Schultze, Kölliker, Hasse, Rüdinger, Waldeyer, Ebner and others; and, after explaining concisely their several views, he proceeds to lay before the reader his own results and conclusions. He tells us that the nerve-epithelium, which contains the terminal distribution of the nerves in the vestibule and ampulla, consists of a deep layer of nuclei, very distinct, surrounded by and embedded in a protoplasmic mass, and above this a superficial layer of cylindrical ciliated cells. The cylindrical cells contain an oval nucleus towards their lower end, which tapers off, while their free upper end presents a cuticular surface from which projects a tuft of cilia. The nerves lose their white substance before entering this nerve-epithelium, and the filaments form networks around the nuclei of the deep layer and between the cylindrical cells, some of the filaments entering these latter cells at their lower extremity.

The acoustic papilla of the cochlea, which corresponds to the organ of Corti in the mammal, he describes as consisting of a superficial layer of cylindrical ciliated cells, very similar to those just alluded to, and below these a thick granular mass which lies on the *membrana basilaris*. This mass contains numerous rounded nuclei irregularly disposed, and a network of nerve-filaments, connected both with these nuclei and with the ciliated cells.

Having given a description of the structure, he proceeds to the difficult question of their function, and enters into the controversy on the cochlea which has been engaging the attention both of the physiologist and the physicist. He first quotes Helmholtz's theory, namely, that the rods of Corti constitute the mechanical arrangement for appreciating the pitch of sounds; then that of Heusen, which gives to the *membrana basilaris* the same function; and finally that of Hasse, who regards the *membrana tectoria* in the same light.

He objects to the theory of Helmholtz on the grounds : firstly, that the rods of the two rows do not correspond so as to form complete arches; secondly, that the nerves do not enter the rods themselves; and lastly, that there are no rods in the bird's cochlea. Against the theory of Heusen several very evident objections are raised, one of which is at once fatal to the view, namely, that in some parts of the bird's cochlea the organ of Corti has no corresponding *membrana basilaris* to lie upon. The author has still less difficulty in dealing with the idea of Hasse, who regards the *membrana tectoria*, a soft mucous mass, as the mechanical appreciator. He therefore scouts altogether the idea of any mechanical explanation, and gives it as his belief that the ciliated cells are influenced directly by the sound-waves. By discarding all mechanical explanations in this manner, he overlooks, in our opinion, several important points. It has been shown by Pritchard, who, he admits, still upholds the original views of Helmholtz in a modified form, that the rods and various component parts of the organ of Corti in mammals are regularly graduated in passing up the spiral of the cochlea and for this reason the cochlea as a whole is undoubtedly

far more perfect in the mammal than in the bird ; therefore we ought not to be surprised surely at finding the addition of an extra aid to the function in the form of rods. Bearing this in mind, the non-existence of rods in the bird's cochlea, does not disprove their mechanical use, seeing that there are two factors to be considered in the appreciating of sounds ; firstly, the apparatus, or in other words, the ear ; and secondly the brain itself. And as no one would suppose that there is any structural difference between the cochlea of what is termed a good or bad musical ear in man, so it is possible, we hold, that the nightingale makes up for its less perfect apparatus by having a brain very sensitive to musical influences.

The author concludes his work by giving some valuable details as to the methods of preparing these delicate structures for examination under the microscope. Taken as a whole, the book is certainly the most complete and comprehensive account of the subject yet published, and we can confidently recommend it to all those specially interested in this branch of histology.

The Cause and Treatment of Rickets. By NORMAN MOORE, M.D., Warden of the College of St. Bartholomew's Hospital. London : Bradbury, Agnew, & Co. 1876.

This pamphlet, which is a thesis for the degree of M.D. in the University of Cambridge, contains some valuable observations upon the etiology of the affection. A table of 200 cases is given, where the principal points in connection with this are exhibited. Thus, as regards suckling, it appears that 40 never received the breast, 23 were weaned at or under the age of seven months, 29 between eight and eleven months, 70 between twelve and sixteen months, and 22 over this. Allowing for 15 cases in which the age is not stated, it follows that 89 per cent. were either weaned at an improper time or never had the breast at all. Farinaceous food was prematurely administered to about one-half the cases : thus—61 commenced it at birth, 32 under the fourth month, 5 between the fourth and sixth month, and 6 at six months. The disease appeared to have no relation to the age or health of the parents. Of 42 cases taken at random, 23 were either first or second children. The date of the commencement of the disease, always difficult to fix, was determined with some degree of certainty in 10 cases. In these the average age was thirteen months, the limit being respectively ten weeks and twenty-two months. Other points worthy of notice was that wasting was present in only 8 ; dentition was almost universally retarded ; intelligence was about normal ; cranio-tabes was never detected. Further, every *post mortem* examination showed a projection above and below each in vertebral substance. The remarks on treatment do little more than strengthen one's faith in cod-liver oil.

The paper is well worth the attention of all interested in children's diseases. It is pleasantly written, and shows indications of considerable erudition. It has the unusual feature of a Gaelic prologue.

On Port-Wine Mark and its Obliteration without Scar. By BALMANNO SQUIRE, M.B. London : Churchill. 1876.

Mr. Squire's treatment of nævus consists in freezing the part by ether spray, scratching it with

an ordinary cataract needle in parallel lines, placing a piece of blotting paper on it before it thaws, and pressing the blotting-paper firmly on the scratched skin for five minutes. If the operation requires to be repeated, the scratches are made transverse to the direction of those made the first time.

G. THIN, M.D.

NEW SCHOOL OF ANATOMY, PHYSIOLOGY, AND OPERATIVE SURGERY.

Mr. Thomas Cooke, F.R.C.S., Senior Assistant Surgeon to the Westminster Hospital, has opened a Preparatory Medical School in connection with his School of Anatomy, the object of which is to instruct young men in both the practice and science of medicine. The intention of this school is that intending medical students shall avail themselves of the excellent practical teaching provided by Mr. Cooke, and his assistants, Mr. George Brown and Mr. Edward Aveling, before joining a hospital. It is reasonably assumed that attendance at a practical establishment of this description would familiarise the student with the subjects he will have to study more in detail in his hospital curriculum, and will give him a decided advantage over the youth who goes straight from school to a hospital course.

The subjects taught at Mr. Cooke's school are anatomy and physiology, *materia medica*, botany and chemistry, and the principles of medicine, surgery, and obstetrics. The time spent in this school will count to the extent of one year or eighteen months as part of the curriculum required by the Royal College of Surgeons of England, and other examining bodies. As an useful preliminary therefore to the regular hospital curriculum, Mr. Cooke's school is highly to be commended as a most useful introductory course.

MISCELLANY.

A NEW hospital, on the plan of isolated pavilions, to contain three hundred beds, is being built in the twentieth *arrondissement* of Paris.

M. LEGUEST has been appointed a Commander, and Professor Germain Sée, of the Faculty of Medicine in Paris, an officer of the Legion of Honour.

THE University of Heidelberg, as well as medical science and practice, has recently sustained a great loss in the death of Dr. Simon, for fifty-three years a professor of surgery therein and a skilful operator.

DR. JOSEPH CARSON, for forty years professor of *materia medica* in the medical department of the University of Pennsylvania, has resigned his position on account of ill health.

IN a recent discussion on the budget in the Chamber of Deputies in Paris, M. Liouville proposed that the salaries of the Professors in the Faculties of Medicine and Science in Paris should be raised from 13,000 to 15,000 francs (520*l.* to 600*l.*). The proposal was supported by M. Cornil, but was not adopted.

THE LANGUAGE OF ANTS.—According to Professor Landois, of Freiburg, ants possess a vocal speech inappreciable by human ears. They are thus enabled to exercise those higher mental faculties to which they owe the development of the advanced social organisation exhibited by them in their communities.

THE Medical Department of the University of Pennsylvania has been investigating the matter of reform in medical education. It decides that a high preliminary examination and a graded three years' course are excellent things, but they are impractical in said University until sufficient funds have been raised to endow the various professorial chairs.

NEW MEDICAL JOURNALS IN OHIO.—Two new medical journals appeared simultaneously in Columbus on June 1: the *Ohio Medical and Surgical Journal*, edited by Professor J. H. Pooley, and the *Ohio Medical Recorder*, edited by Drs. J. W. Hamilton and J. F. Baldwin. Both are to be published monthly. Dr. Pooley's first issue contains ninety-six pages of reading matter, including several original papers, clinical records, reviews, etc. The *Recorder* has forty-eight pages, but uses a smaller type.

DR. FRANK BULLER has been appointed oculist and aurist to the Montreal General Hospital. The appointment was made upon the unanimous recommendation of the medical board, who were of opinion, that from the long experience of Dr. Buller in the Moorfields Hospital and on the continent, his assistance in the work in the hospital would be a great advantage both to the public and to themselves. Dr. Buller has already delivered a short course of extra-academical lectures on ophthalmology in connection with the summer session of McGill College.

RELIGION AND HYGIENE.—An old adage already proclaims the near approximation of cleanliness to godliness; it is left to a French doctor, M. Dubert, to suggest the same union between hygiene and holiness. In a paper read by him at a recent scientific congress on the Mortality of Young Children, he attributes this deplorable result in great measure to the ignorance of the mothers, who feed their infants in an improper manner. To remedy this fatal ignorance, M. Dubert makes the very practical suggestion that a short appendix containing elementary precepts on feeding and rearing infants, should be printed at the end of prayer-books, missals, and religious books generally.

CLINICAL INSTRUCTION IN MENTAL DISEASES IN PARIS.—M. de Marcère, the French Minister of the Interior, has, on the application of MM. Liouville and Robin, sanctioned the re-establishment of clinical lectures in the St. Anne, Salpêtrière, and Bicêtre Asylums, which were suppressed two years ago by the Prefect of the Seine. The closure of those institutions against clinical instruction excited at the time strong remonstrances from the French medical press, but without effect. We are glad to hear of the removal of the restriction, which must have had a very injurious influence on an important branch of professional education.

MODERN ADVANTAGES.—Archæological researches sometimes help to remind us of the boons of modern civilisation. Flickiger finds from reference to the tariff of the city of Nordhausen near Göttingen, that in 1657 tea—*Herba theæ*—was there a pharmaceutical article. It also occurs in the tariff of Liegnitz, in Silesia, in 1662, under its Chinese name, *Herba Shak*; it then commanded a most extraordinary price—namely, fifteen florins a handful. Cacao seeds and chocolate were to be found with German pharmacutists as early as 1656 and 1683 ('Doc,' pp. 53 and 69), and Coffee—'*Bon Cofi Grana*'—in 1683 in the pharmaceutical office of the court of Dresden.

THE BOYLSTON MEDICAL PRIZES.—Dr. W. Gill Wylie, of New York, has received the Boylston prize of 300 dollars, for an essay on 'Civil Hospital Construction,' and Dr. Mary Putnam Jacobi the prize of 200 dollars for an essay on the subject, 'Do women require mental and bodily rest during menstruation?' The questions proposed for next year are as follows: (1.) Are epidemics and so-called contagious diseases necessarily dependent upon material agencies, acting through the stomach or otherwise? (2.) Athletic sports, training, violent exercises, etc., as now practised by young men; their temporary or permanent influence on the health. The following are the questions proposed for 1878. (1.) Antiseptic treatment. What are its essential details? How are they best carried out in practical form? (2.) Diphtheria: its causes, diagnosis, and treatment.

HYGIENE IN THE RUSSIAN SCHOOLS OF MEDICINE.—The Russian Government exhibited at the Brussels Exhibition for the Saving of Life, some specimens of the models used for illustrating hygiene in Russian schools. The composition of the human body is shown by a series of jars, which contain separately the approximate quantity of the substances that go to make up the human frame. First, a large glass barrel, holding about 50 kilogrammes of water, is shown, and this forms 72 per cent. of the total ingredients. In smaller vessels are the gelatine, the albumen, the fat, the phosphate and carbonate of lime, and divers salts which help to constitute the mortal part of man. The pupils having thus learnt of what they are made, are told how to maintain the natural balance. They are taught of what various kinds of food consist. In a glass tube there is exhibited so much water, so much albumen, so much cellulose, sugar, starch, etc., and the outside is marked 'cabbage,' or 'cucumber.' There are jars of black bullock's blood to be shaken up with air in order to show how oxygen reddens and revives the blood in the lungs. There are also jars with lime-water and a breathing tube so that the pupil can breathe in and see the water curdle at the action of the carbonic acid. Another breathing apparatus experiment shows that this carbonic acid is fatal to the flame of a taper as it would be to human life, and as it ultimately is to the unhappy dogs periodically thrust for the instruction of the traveller into the Grotto del Cane, near the Avernian lake in Southern Italy. By another of the Russian models a striking sanitary lesson is taught. The exhibitor breathes into one side of a box, which is divided into two by a strong brick wall. The other side of the box is tapped by a tube which ends just above the flame of a candle. When the exhibitor has poured carbonic acid from his breath into one side of the box it passes through the bricks, and coming through the tube falls down (being heavier than air) upon the candle and extinguishes it. Thus the learner is taught that noxious gases are not kept out by brick walls.

RUDOLPH VIRCHOW.—A writer in the *New York Medical Record* gives the following account of Rudolph Virchow, the eminent German pathologist. Virchow is eminent in the political as well as in the medical line. His tenets, at variance with those of the Chancellor of the Empire, and in sympathy with that large radical party of Germany whose ideal may be seen in nearly every European government of to-day, call it by whatever name you please, liberalism, radicalism, or conservatism, have developed an iron will and a bitter sarcasm which make him a species of terror to the government. In other ways he is remarkable. Always late at his lecture, and appearing now but twice a week, he has time enough, apparently, for the numerous demands made upon him. On the same day he is to be seen from nine to eleven A.M. in the Pathologisches Institut, demonstrating, with a vast array of material, cellular pathology; and from five to seven or eight P.M. in the Chamber of Deputies of Prussia, of which he was recently elected vice-president, over the nomination of his predecessor; later, hard at work in the Royal Geographical Society. Besides these official appointments he is chief editor of a popular journal of science, contributes occa-

sionally an article to scientific bodies, and gives popular lectures in the winter. It may not be generally known that in the revolution of 1848 he fought as a common soldier behind the trenches; that he was forced to abandon his professorship here on account of his political doctrines, and that he went to Würzburg, where the book of his life—the exposition of the cellular pathology—was written; that the government was obliged to recall him to his department in the university on account of the urgent demand of scientific men, who recognised his worth by the new book; that later Prince Bismarck challenged him to a duel, whose acceptance he had the courage to refuse; these and many other events of his life make Rudolph Virchow one of the most conspicuous men of the day in Germany. It is said that he regrets the comment not long ago made about him, that he was a severe critic as to the merits of other men. Virchow is poor, lives on the second flight, and complains that he cannot live as a gentleman of his standing should.

THE VIVISECTION BILL.—In Dr. McKendrick's opening address in the department of Anatomy and Physiology, Section of Biology, at the meeting in Glasgow of the British Association for the Advancement of Science, he made the following remarks: 'These sciences present different views of the same great system of truth. Anatomy is the science of organic form, while physiology is that of organic function. The kindred science of physiology has for its object the elucidation of function, and it has in addition to the methods of anatomy—viz., dissection, description, and comparison—those of pathological observation and experimentation. It is confessedly the science most difficult of all to prosecute. In the further prosecution of physiology as a physical science, which it really is, experimental inquiry with the aid of precise instruments, and the facts derived from the observation of the course and effects of disease, seem to me to be the two lines of evidence which will in future weigh with us in coming to just conclusions. I make these remarks regarding the value of the experimental method in physiology because we cannot forget the attempt which has recently been made to restrict us in the use of this important aid in prosecuting our science. I shall not enter again upon the controversy which has raged in this country regarding experiments upon animals, because by the passing of the bill a practical solution of the question has been arrived at in the meantime, and it now becomes us as good citizens to do all in our power to carry out the provisions of the Act and give it a fair trial. I may say, however, that I always recognised the right of the public to agitate on this question if they considered unnecessary cruelty was being perpetrated. I hope the day will never come when tales of suffering inflicted either on man or beast would be heard by us with calm indifference. It was not wise, therefore, to meet this agitation with contempt and scorn for the ignorance of those who carried it on, and it seems to me that the appointment of a Royal Commission to investigate the facts of the case was the best thing that could have been done by the government. The commission was composed of men likely by character and previous training to ascertain the truth. No one can read the evidence in the blue-book and the report founded thereon without coming to the conclusion that the case of those who raised the outcry against physiologists in this country completely broke down. On considering this report, the government brought in a bill, certain of the provisions of which seemed not only oppressive to physiologists, but were calculated, if carried into law, to impede the progress of science. The members of the medical profession, who knew the value of the experimental method in physiological research, and who were painfully conscious of the many imperfections of the art due to the want of knowledge, were now aroused, and that aided the physiologists of the country in making representations to the government which were favourably received, and which led to important modifications in the bill. That bill has now passed into law, and I appeal to our opponents to desist from further agitation.'

Authors of Papers, Theses, &c., will assist in the preparation of summaries by our reporters, by forwarding separate copies of their works.

BRUGNOLI ON ANOREXIA.

The sixth volume (third series) of the *Memorie dell' Accademia delle Scienze dell' Istituto di Bologna* contains an article on anorexia by Professor Brugnoli, of which the following is an abridged translation.

Anorexia, the morbid condition which consists in the want of appetite for food, and even in complete aversion, was formerly considered as a disease in itself and well described, but is now regarded only as a symptom. It is, in fact, often enough met with as a constant symptom in all febrile diseases, and in very many of those which have taken seat in the stomach; it is often an accidental symptom in cases of disease of the brain and of the nervous system, of chlorosis, and of many diseases of the urinary organs. It is true that it sometimes prevails to such an extent as to attract special attention in the form of protracted fasting, in cases of hysteria and nervous affections of organic life. Many cases have indeed been recorded of protracted fasting without detriment to the strength or to nutrition; such cases have been recorded by Haller, Beccari, and Vallen- zasca; and Dr. Brugnoli himself has related a case of fasting during fifty days in his essay on the therapeutic use of nux vomica. But, in all these cases, the singularity consists in the long want of alimentation without a corresponding impairment of nutrition. And in examining the collection of symptoms observed, it is plainly seen that the inability to take part is an epiphenomenon, a symptom of a complex neurosis, of altered innervation of a part of the nervous system, and especially of that which presides over the functions of organic life. To these symptoms are frequently added others indicating psychical changes, and affections of sensation or of motion.

But cases of anorexia without other symptoms than the results which may be expected to attend the want of nutriment, are very rare. Dr. Brugnoli had not met with such a case in his own practice, nor in the recorded observations of others. Within a short space of time, however, he has met with two cases, in which the aversion to food, amounting almost to inability to take into the stomach, was the sole morbid symptom; it continued about two years, and ended fatally. The cases are as follows.

CASE 1.—The subject of this case was a young lady belonging to a noble family in Bologna, who had enjoyed good health up to her sixteenth year. Her parents were healthy, and there was no suspicion of hereditary disease, beyond a tendency to disorder of the stomach in the father's family. She first menstruated at the age of fourteen; and at that time, as regarded development, she had the appearance of a girl eighteen years of age. She did not habitually eat much, and preferred broths and soups in abun-

dance, to meat. When she was nearly seventeen years old, her parents observed that she ate less food than usual; she no longer took meat, or any other nutritious food, except soup, of which the quantity was less than usual. This was attributed to a false alarm of thieves in the house which the family received late one night, but the patient declared that she had not been affected by it. On careful examination no structural change could be detected, nor was any other function altered; deglutition was free, the food when it reached the stomach was digested regularly without trouble or pain, defecation was normal, and menstruation was regular; the urine, however, was rather abundant, and she had much thirst. These two circumstances led to a suspicion of diabetes, which, was, however, dissipated by examination of the urine several times in the course of her illness. During several months, nutrition and muscular force were not much affected, although the disease increased in spite of various medicines. At first, with the view of combating catarrhal gastritis, the remedies administered were alkalis, Vichy water, lime-water, nux vomica, and opium in various forms; but all without avail. At dinner time, when urged by the family to eat, she would put food in her mouth and chew it, and then declare that she could not swallow it, or do so with great effort. Dr. Brugnoli several times passed the œsophageal sound, but never found any signs of stricture. After consultation with Professor Roncati, it was determined to treat the case as one of dyspepsia, and lemonade with hydrochloric acid, pepsin, and various remedies to improve digestion were used, but without any improvement. Other remedies were also tried; but although the treatment ordered was steadily carried out by the patient, the disorder continued to make slow progress, and interference with nutrition became evident in the form of disappearance of the fat from the muscles of the neck and face. Thus matters went on for more than a year, and still sufficient muscular strength remained to enable the patient to take long walks; the catamenia, however, ceased. It was imagined by some that there was erotic disorder; but no sign of this could be detected, and the girl herself declared that her inclination was for the cloister. After some time, she entered a Dominican convent in Rome, where a sister already was. She bore the journey well. In Rome, she was placed under the care of Professor Rudel, who finding no visceral alterations, hoped that with change of climate and mode of living, and with new moral impressions, the chain of phenomena of disordered innervation would be broken and a cure effected. She continued, however, to lose flesh and strength, and died about three months after her arrival in Rome.

CASE 2.—Annetta M. was born towards the end of 1852 of healthy and robust parents; her mother, however, had in her fifteenth year a sudden and dangerous attack of what appears to have been meningeal hæmorrhage. Her childhood was healthy; she had on one occasion a glandular swelling of the neck, probably of traumatic origin; and there was no reason to suspect scrofula or other constitutional vice. At the age of fourteen, she first menstruated; and was then developed beyond the common. She was now placed in a college, where she grew even more than before, although she adapted herself to the regular mode of living. She had, however, an attack of rheumatic fever, in consequence of being subjected to changes

of temperature during dramatic performances. On leaving the college she appeared in florid health, and was remarkably tall. From her infancy she had been accustomed to eat much and often, especially bread; she took food five or six times in a day. This, however, was attributed to her large growth. This condition continued till her twenty-first year, when, in July, 1873, a remarkable diminution in the amount of her food was observed. She did not complain of pain or trouble, but sometimes said that she had a sensation of tension from the pharynx to the stomach; this sensation, however, she had formerly felt on other occasions, and had removed it by eating. But she now said that she did not feel hunger, and that she could not eat because the food *did not go down*. This phenomenon lasted for seventeen months, up to the time of her death; it sometimes, however, disappeared for a few days. This generally happened either before the appearance of the catamenia or immediately afterwards. The hopes then raised, however, did not last more than three days. A curious phenomenon was that she sometimes awoke in the course of the night, feeling as if she could eat freely, and ate abundantly, even things difficult of digestion, without feeling any trouble; but the next morning the event would be forgotten by her as if it had been a dream. For more than ten months there was no other symptom than inability to take food into her stomach, and steadily increasing loss of flesh. About June, 1874, menstruation ceased; she had erratic febrile attacks in the evening, and there was some dry cough. As time passed on, the febrile attacks became more marked; in fact, during the whole day there was a slow febricula, and a careful examination of her chest detected some coarse respiration in parts, which gave rise to the idea that there might be acute miliary tuberculosis. Some small white spots like miliary tubercle were observed on the arches of the palate and the posterior wall of the pharynx. The patient died on November 20, with all the symptoms of the asphyxial form of pulmonary consumption.

In the treatment of this case, the object sought was to modify the conditions of the stomach; and among the remedies used were bicarbonate of soda, magnesia, lime-water, calomel, opium, nux vomica, bromide of potassium, revulsives, iodide of potassium, arsenic, sulphites of alkalies, and Porretta-water. None of these, however, had any effect.

In commenting on these cases, Professor Brugnoli remarks that no one would doubt that in both instances death was the result of the insufficient quantity of food introduced into the stomach, in consequence of which the tissue-changes were interfered with. He continues:

But the second at least of the cases succumbed to a supervening disease, a sequel rather than a complication—acute miliary tubercle. And even if Buhl's theory of its origin from a local focus of infection be generally true (and observations in its favour are increasing in number), there are still cases where, in spite of most minute research, no focus can be found to which the origin of the infection can be traced. I have several times seen acute miliary tubercle develop and run a rapid course after a prolonged fright, in individuals who had shown no signs of having foci of suppuration of any kind, and in whom none were found at the necropsy. I am hence of opinion that a perversion of the blood-making process, whether through the influence of altered innervation or of

insufficient nutrition, may give rise to a special diathesis; an alteration of the blood of such a nature as to cause the formation of grey tubercle. The idea that deficient nutrition was the cause of the tuberculosis is supported by the observation of alienists, that in refusal to take food on the part of the insane, when forced alimentation cannot be perfectly carried out, the cases end in acute miliary tuberculosis.

Passing to the consideration of the anorexia, it is certain that the idea of its having been symptomatic of disease of the stomach must be excluded. The absence of pain and of interference with digestion, the results of examination of the epigastrium, the freedom from vomiting, all proved this; moreover, however severe a disease of the stomach might have been, such as cancer, or degeneration of the muscular fibres, it would not have produced such marked anorexia, nor would this have been the only symptom.

It is then manifest that the difficulty of taking food arose from a disturbance of the functions which make up the act of mastication and deglutition. It was not disgust at food that prevented the patients from eating; they took food into the mouth without aversion, but the difficulty arose when they were about to transpose it to the pharyngo-œsophageal canal. As has already been observed, the description of this symptom was so distinct that I was induced to make an examination with the œsophageal bougie in order to exclude all idea of stricture; besides, on inviting the patient to eat in my presence, the first morsels went down readily, but very soon she declared that this could no longer be done, so great was the resistance.

In considering the appetite for food, and the pleasant sensation experienced in eating, it seems to me that it may be divided into two parts; first, when the morsel is formed in the mouth, and we make it pass over the nervous papillæ of the tongue and oral cavity; second, when it is propelled into the throat. These two forms of sensation appear to me so different that they should be kept separate. We see in fact some individuals who feel the greatest pleasure in slowly tasting the food in the mouth, retaining it there for a long time; whilst others feel so much pleasure in swallowing, that they do it so eagerly as to only incompletely perform the division, and insalivation of the food. Physiology teaches us that the act of mastication, up to the time when the tongue is applied to the palate to push the morsel towards the isthmus faucium, is subject to the will; but that all the other consecutive movements of deglutition are involuntary, and belong to reflex actions excited by the impression produced by the food on the posterior part of the tongue. It appears to me that the anorexia in my two patients must be attributed either to a perversion of the gustatory sensation on transferring the food to the throat, which, instead of being pleasurable and appetising, was a source of trouble and disgust; or that the impression produced by the morsel of food on the dorsum of the tongue, was incapable of exciting the involuntary reflex action.

But to what part of the nervous system or to what nerves must the morbid phenomena be referred? It is indeed true that the glosso-pharyngeal nerves supply the base of the tongue and the velum palati; on the other hand, the vagi nerves have a great share in deglutition, both as sensory and as motor nerves. Physiology, however, in spite of much

labour and experiment made with the view of determining the action of the various nerves of the pharyngo-laryngeal apparatus in deglutition, has still left much in doubt; and I cannot lay aside the belief that anorexia of the kind which I have described has its origin and seat in one of the above-named nerves. But, on the other hand, knowing that the feeling of hunger is lost in animals whose cerebral hemispheres are removed; that in many diseases of the brain and in many forms of mental observation anorexia is a very prominent symptom; that it is seen to be produced by mental disturbance, by narcotics, etc.; we are led to consider whether the seat of anorexia may not be still more central, that is, in the brain. And we are the more warranted in adopting this supposition, knowing as we do that central cerebral diseases give rise to bulimia, and sialorrhœa, and vomiting, and saccharine diabetes. In the two cases related, the idea that the change which produced the anorexia lay in the brain cannot be excluded, notwithstanding the absence of other indications. Perhaps a careful necropsy would have thrown a ray of light on this difficult question. I certainly wished to have one, but my desire could not be gratified.

In concluding, Professor Brugnoli expresses the opinion that anorexia ought to have a place as a disease in nosology, at least until physiology and pathology shall have accounted for all the acts of healthy and diseased life with regard to the functions of the nervous system.

BULL ON THE INFLUENCE OF NEURALGIA OF THE TRIGEMINUS IN CAUSING IRITIS AND CHOROIDITIS, AND ITS PATHOLOGICAL SIGNIFICANCE.

DR. CHARLES S. BULL, ophthalmic surgeon to Charity Hospital, and assistant surgeon to the New York Eye Infirmary, writes as follows in the *New York Medical Record* for August 19. For more than a year past my attention has been attracted by certain phenomena of a nervous nature, in connection with iritis and choroiditis, which seem to me to illustrate the intimate connection which exists between neuralgia of the trigeminus and intraocular inflammation, when involving the iris and choroid; and the two forms of disease, neuritis of one or more branches of the fifth nerve, on the one hand, and intercurrent iritis or choroiditis, on the other, I think, bear the relation to each other of cause and effect. This view I have been induced to consider highly probable, from my own observation of seven cases.

The pathology of the trigeminus is still very obscure, and investigators are still groping in the dark, or in what, at best, is a very subdued light, for some slight ray that may help their footsteps along in the right direction towards a full comprehension of the subject.

Clinical facts are what we all need, either in advocating or in opposing a theory; and, therefore, to the broad field of clinical observation must we look for aid in elucidating the difficulties which overhang still a very important subject. Neuralgia of the trigeminus is an affection of great interest, not only on account of its frequent occurrence and obstinate resistance to treatment, but also on account of its connection with other lesions, which are sometimes of a most intricate nature. Many pages have been

written upon the single subject of herpes zoster ophthalmicus, in connection with neuralgia of different branches of the supraorbital and infraorbital nerves, and a great deal of valuable time and arduous labour has been spent in attempting to account satisfactorily for the occurrence of necrotic inflammation of the cornea and iris, which is met with in this disease.

Neuralgia of the fifth nerve is usually complicated with secondary affections of other nerves, which are intimately connected with those that are the original seat of the pain. When the pain in the nerve is the result of direct injury to the nerve-trunk, whether by external violence, by the mechanical pressure of a tumour, or by the nerve becoming involved in some inflammatory or ulcerative process, the general condition of the patient produces scarcely any effect. In general migraine it is a well known fact that the pain spreads to every terminal branch of the ophthalmic division; the eye on the affected side is deeply injected; there are lachrymation, photophobia, and partial ptosis, with occasional spasmodic contractions of the orbicular muscle, and cloudy vision.

In a tabulated report of 128 cases of neuralgia of the fifth nerve in the *Arch. Gén. de Médecine*, Notta says that the retina was completely or almost paralysed in ten cases; there was dilatation of the conjunctival vessels in thirty-four cases; permanent tonic spasm, not due to photophobia, in four cases; paralysis of the third nerve, causing ptosis, in six cases; and divergent strabismus in three cases. The pupil was dilated in three cases, and contracted in two cases, without impaired vision. In three others there was a dilated pupil with impaired vision. He also mentions among the complications, glaucoma and ulceration of the cornea.

Now the relations of the fifth nerve to so important an organ as the eye, tend to call our attention strongly to the phenomena that accompany its morbid conditions. Not merely the circulation of the parts supplied by this nerve becomes affected, but also the nutrition of the tissues. Anstie tells us that the periosteum of bone and the fibrous fasciæ in the neighbourhood of the painful points not unfrequently take on a condition of subacute inflammation, with marked thickening and tenderness on pressure. He considers also that glaucoma is in many cases of nervous origin, and in this opinion all ophthalmologists will coincide. In regard to this subject, Bowman first called attention to the interesting fact that, in certain glaucomatous conditions, there occurs a rapid change in the intraocular pressure; sometimes an increase, at others a decrease. The anomalies of tension are generally transient and of a varying nature. Of course we leave out of consideration all those conditions described as atrophy of the eyeball, in which the softness of the globe depends on disorganisation of the tissues and an altered intraocular circulation. We are still very ignorant of the physiological conditions which are here concerned. The hypotonia, or loss of tension, is constantly associated with contraction of the pupil. The patient complains of a dull pain in the eye, or of stabbing pains in the orbit, and in many cases there is violent neuralgia, which often merges into migraine. The spontaneous neuralgic pains generally occur periodically, often accompanied by injection of the conjunctiva and lachrymation. During this rapid change of tension, we should always carefully note the relation existing between

the hypotonia and the size of the pupil; when the pupil is narrowest the eye is softest, and the neuralgia generally the most severe. The hypotonia is very often accompanied by slight chemosis of the conjunctiva, and by small delicate vesicles or phlyctenulæ. Another symptom is the local change of temperature, generally an increase, though occasionally a diminution has been observed. There is also congestion of the corresponding half of the face, and hyperæmia and swelling of the nasal mucous membrane. These cases differ from one another in the prominence of the individual symptoms; in one there are merely changes in tension, in another there is increase of temperature, while in a third the functional symptoms are the most important. Jonathan Hutchinson has written much upon the subject in the published reports of the Moorfields Ophthalmic Hospital, and he has come to the following conclusions.

1st. The whole subject of reflex paralysis and reflex disturbance of nutrition is obscure and difficult of satisfactory proof. In some cases it is not at all certain that a central disease does not exist, to which both the lesion of sensation and the lesion of nutrition are alike due.

2nd. In many cases the changes are probably due to influences exerted through the vaso-motor nerves only, by which are induced alterations of the blood-supply to the affected part.

3rd. It is, however, probable that nutritive alterations may be induced through the nervous system, independently of any primary change in the calibre of the blood-vessels.

He cites, in detail, seventeen cases, one of which was glaucoma of one eye, occurring during a severe attack of neuralgia of the fifth nerve.

Comparatively recent investigations have proven that the phenomena of recurrent sensibility occur in almost all nerves. It is tolerably rare in neuralgia to find the whole of the nerve-trunk the seat of pain. The pain is commonly referred to certain limited spots, pressure upon which will at once induce it. As Valleix first pointed out, the most superficial nerves are principally affected, and their points of emergence on the surface the chief seats of pain. Arloing and Tripier proved experimentally that all nerves—motor, sensitive, and sensory-motor—possess recurrent fibres, which become more numerous as the nerve approaches the periphery, and decrease in number as we go back towards the centre, until they finally disappear altogether. As these recurrent fibres have never been seen to terminate in the thickness of the nerve-bundles, they may be assumed, from the characters noted, to end at different points in the tissues adjoining nerve-trunks or their branches. It is these fibres that, in certain cases of neuralgia, would be affected by morbid agents, which may possibly explain the occurrence of the isolated painful spots on nerve-trunks and their branches. Another argument in favour of this hypothesis, Arloing and Tripier find in the diminution, or even total disappearance, of these fibres above the points indicated by Valleix, as the special seats of neuralgic pain. It would be erroneous to assert that these fibres are alone affected in neuralgia; yet equally far from the truth to state that spontaneous neuralgia follows the course of the nerve. They also consider it supposable that the morbid agency acts at once, both on direct and recurrent fibres; consequently if we examine the mode of extension of the neuralgia, from the disordered nerve to one that is sound, an addi-

tional argument for their theory is afforded. It is certain that extension very often takes place through the medium of the nerve-centres, as is exemplified in the frequent coincidence of trifacial neuralgia with pain in the cervical nerves. In trifacial neuralgia it is not uncommon for the pain to glance from the ophthalmic branch to the mastoid process and upper part of the neck.

In cases of traumatic neuralgia, it is impossible accurately to determine always the amount of nerve-lesion in individual cases, and hence it is not always possible to study the relation between the extent of nerve-injury and the amount of consequent shock.

It might be supposed from the frequent occurrence of injuries to the eyeball and orbital margins, that wounds of the infraorbital and supraorbital nerves would be not uncommon accidents; but this is not so. They are sufficiently rare, though they do occur. Weir Mitchell has seen severe neuralgia of these nerves, where both had been contused by a single blow from the head of a cane.

Charcot mentions the case of a man, who, after receiving a violent blow upon the side of the head, which fractured the outer table of the parietal and adjoining portion of the frontal bone, complained of constant violent pain in the branches of the frontal and occipital nerves. Later, the neuralgia became localised in the right eye, orbit, and ear; the eye became red and prominent, the conjunctiva œdematous, and the upper lid paralysed. The cornea was hazy, and there was iritis with synechiæ.

Perhaps the most curious and interesting feature of these cases of iritis and choroiditis, is the strange variations in intraocular pressure, and their connection with the activity of the inflammation and the severity of the neuralgia. Close observation of the seven cases which I have been able to follow out, have led me to the conclusion that, as a rule, the beginning of the pain leads to a slight diminution of tension, which rapidly becomes more marked as the inflammatory action proceeds, and is lowest when the latter has reached its height. Without entering upon a discussion of the subject of intraocular pressure, let me say a few words in regard to the influence of the fifth nerve.

By irritating the medulla at the deep origin of the fifth nerve, the intraocular pressure is always increased, and lasts some time after cessation of the irritation. The result of irritation of the fifth is always the same, whether the cervical sympathetic was previously divided or not. The explanation is probably as follows. The first cause of increased tension is an active dilatation of the blood-vessels of the choroid and iris; the fact that the irritation of the fifth nerve increases the tension, even after evacuation of the aqueous humour, proves that a secretion or transudation of the ocular fluids occurs somewhere during this irritation. It is further proved by another experiment; if we divide the spinal cord between the occiput and the third cervical vertebræ, no considerable increase of intraocular tension is produced, but when the fifth nerve is irritated in the same animal, there is.

A final legitimate conclusion may be stated somewhat as follows. In some way, either peripherically or centrally, the trigeminus is irritated; as the immediate result, there occurs a slight increase of intraocular tension, caused by increased secretion of fluid in the posterior segment of the eyeball, by which the iris and lens are pushed forward; by the pulling of the zonula upon the latter, a new irritation

is set up, which again acts on the secretory nerves, and, of course, causes an increase of tension. As a secondary result of the pressure, the points of exit of the *venæ vorticosæ* are narrowed, and we get disturbance of the circulation. But the cause of the intercurrent inflammatory action is still undecided and obscure.

As a *résumé* of still later investigations of Hippel and Grünhagen, the following may be offered. The trigeminus, by dilatation of the vessels of the iris and choroid, and by diminution of the resistance to osmosis, can cause an increase of the intraocular pressure. The sympathetic, as the specific ocular nerve, when irritated at the superior cervical ganglion, causes diminution of the intraocular tension. In the history of glaucomatous cases, as well as of those of essential phthisis bulbi, there is an irritated state of the ciliary nerves. Now, since all sensory nerves stand in reflex connection with the vaso-motor nerves in general, and particularly with those of the eye, the irritated condition of the ciliary nerves may easily extend to the vaso-motor nerves of the eye, and may induce periodically or permanently contraction of the blood-vessels, a lessened supply of blood, and a consequent diminution of the tension of the eye. This I hold to be the explanation of the phenomenon of diminished tension, which occurred in all the cases of iritis and choroiditis that formed the basis for this paper. In all of them it was present, and in most of them very marked, and always showed an intimate connection with the state of the pupil and the degree of inflammatory action.

It is well known that, in the majority of cases, the affections of the eye, which occur simultaneously with or subsequent to neuralgia of the peripheral branches of the trigeminus, consist in periocular neuralgia, accommodative asthenopia, spasms of the orbicular and facial muscles, and the more serious lesions of the cornea and conjunctiva. We also know that these attacks of neuralgia are due to an inflammation of one or more of the terminal twigs of the ophthalmic division of the fifth. Now it is a matter of experience that the supraorbital or frontal branch is the most often inflamed, and the neuralgia is very often characterised by evening exacerbations. Galezowski cites a remarkable case of this kind of neuralgia in a patient from whom he had removed one eye three years before for hæmorrhagic glaucoma, and had done an iridectomy in the other for chronic glaucoma. In this eye, vision was restored and remained good for three years. The patient was then attacked by periodical neuralgia of the orbital margins, which was very violent; the eye became red, and vision was considerably impaired. Galezowski at first thought that it was a return of the glaucoma, but a closer examination showed that the disturbed vision was due to excessive lachrymation, and the case proved to be a true neuritis of the supraorbital nerve, which he cured by a succession of blisters.

If this frontal neuritis be not arrested, and if the neuralgic symptoms be prolonged during weeks and months, there result, very often, spasmodic contractions of the muscles of the face and lids. Here the case becomes more serious, and we must resort to subcutaneous division of the supraorbital and infra-orbital nerves, and even to an exsection of a portion of them.

Some authors are inclined to believe that, if the inflammatory action affect the peripheral twig, the

eye complications are very superficial, are most often purely neuralgic and rarely inflammatory; and that the most serious lesions of the iris and choroid are only met with when a deeper portion of the trigeminus is involved, viz. the ganglion of Gasser; and that when a cerebral lesion is at the bottom of the trouble, there is such an alteration in the nutritive centres of the eye that the most serious results are here met with. This reasoning I believe to be faulty, for cases of grave choroidal lesion certainly do occur where vision is practically abolished, where there is surely no cerebral lesion present, nor even any suspicion of one, but where the intraocular trouble is due solely to peripheral irritation.

In glancing over the current ophthalmic literature of the past few years, we are surprised to find how few cases there are published of grave lesion following neuralgic affections of the fifth nerve; and still more rare are those cases which are not glaucomatous, in which there is a *diminution* of tension associated with iritis or irido-choroiditis.

In the Transactions of the American Ophthalmological Society for 1870, Roosa mentions a case of conjunctival and corneal lesion with partial ptosis, in which, for nine months, there occurred every week with great regularity conjunctival injection of one eye with neuralgia, both ciliary and frontal, contraction and sluggishness of the pupil, lachrymation and diminution of tension. Only the ocular conjunctiva was injected, especially on the nasal side, but there were never any signs of herpes. The attack lasted several hours, and no treatment was of much use. After nine months the attacks became rarer, and finally ceased.

Noyes somewhere reports a case of unilateral herpes zoster ophthalmicus with bilateral blindness, which is of interest in view of the immediate cause of the loss of vision. There was the usual eruption on the left side of the face, accompanied by very violent and continuous neuralgia of the same side. The *left* eye became blind during the attack, but not from ulceration of the cornea. Ten months later the right eye became inflamed and vision was lost, just as the left one was, from irido-choroiditis, without any eruption on the right side of the face.

It may seem to some that seven cases are far too few to draw conclusions from, but we certainly can learn something from a careful observation of even this small number. In five of the cases, the patients had been neuralgic for a number of years, and in one of these since early childhood. Two cases were of traumatic origin—that is, the neuralgia was caused by direct injury to the nerve-branches, and in both of them the nerves were involved in the resulting cicatrices. In all seven the same symptoms were noted.

After the neuralgia had lasted for some time, usually months, a very violent attack occurred, accompanied by marked conjunctival injection and diminished tension, followed by a sharp iritis, during which the tension rapidly decreased, the pupil remained contracted in spite of atropine, though not always from adhesions, and the neuralgia ceased. During the height of the inflammation the tension remained diminished, but when the inflammation began to yield, the tension began to increase and the pupil to dilate. With each fresh relapse, the same symptoms followed in usually the same order, and the choroid generally soon became involved. In only one case was there ever any conjunctival herpes, and in this case the vesicles always ap-

peared at the inner angle, near the caruncle. The prognosis is almost always bad, for the neuralgic habit is almost permanent, and with each attack of neuralgia the eye is almost sure to sympathise after the first attack of iritis. Of course, when the choroid is involved, the aspect of the case becomes a grave one.

Dr. Bull here relates several cases, of which the summaries are as follows :

CASE I. Long-continued neuralgia of frontal nerve, followed by suppurative irido-choroiditis and sympathetic iritis in the other eye.

CASE II. Irido-choroiditis following violent and continued frontal neuralgia, of possibly traumatic origin.

CASE III. Irido-choroiditis, with diminished tension following contused and lacerated wound of the forehead in the region of the frontal nerve, with obstinate neuralgia.

CASE IV. Optic neuritis, followed by irido-choroiditis, preceded by intense neuralgia of the scalp and face of the right side, of traumatic origin.

CASE V. Irido-choroiditis following long-continued neuralgia of the first and second branches of the fifth nerve, with diminished tension, and ending in phthisis bulbi.

CASE VI. Irido-choroiditis with marked diminution of tension, preceded for several months by neuralgia of the frontal nerve, following fracture of the bones of the face.

CASE VII. Long-continued facial neuralgia followed by iritis with deposit on the membrane of Descemet, and subsequently choroiditis with exudation, with frequent relapses.

As regards the operation of iridectomy in these cases, a few words may not be amiss. Since the performance of this operation for making an artificial pupil, and more recently as a remedy for glaucoma, has made it widely known, it has become of such general practice in all sorts of cases, as to bring down upon itself from ophthalmologists during the past few years an amount of odium which is, I think, undeserved. The reaction has been too violent, and the pendulum of surgical opinion has swung so far in the opposite direction as to excite apprehensions that it will not swing back. There is no doubt that the operation has been performed in many cases, not only where it was not indicated, but also in many where it was strongly contra-indicated, as in cases of violent inflammatory action. Its ultimate disturbing influence upon vision has not been sufficiently considered by its too ardent advocates, and like many another medical or surgical remedy, it has been regarded as a sort of universal panacea for most of the deeper lesions of the eye. But recognising this fact, it will not by any means do to reject it, as too many have done, and consign it to the limbo of surgical oblivion.

In the subject under consideration, in iritis and choroiditis, we may still safely trust ourselves to the dictum of our great master, von Graefe, who writes as follows.

‘It is not iritis itself, the single acute attack, which in the majority of cases threatens the vision or even the loss of the eye, but the frequent relapses, which always cause new exudations into the pupil, and frequently its complete closure. In many of these cases the real origin of the evil lies in the eye itself, in the posterior synechiæ. The periodic ciliary neurosis, so common in these cases, often depends solely on the presence of these posterior synechiæ.

The closure of the pupil forms the point of origin of further complications, particularly chronic choroiditis and phthisis bulbi. Where atropine fails to break up the synechiæ, and relapses continue to occur, there is but one resource left us, the performance of an iridectomy, which should be so done as to break or tear away the broadest synechiæ, and thus do away with the exciting cause.’

From my own experience, while admitting that even an iridectomy does not always succeed in preventing the relapses in these cases complicated by a diseased trigeminus, yet I certainly would not postpone the operation till the eye had become seriously damaged by the relapses, but would do it as soon as it was evident that the ordinary means of treatment had failed.

BÓKAI ON POSTPHARYNGEAL ABSCESS IN CHILDREN.

A LARGE portion of the last number of the *Fahrbuch für Kinderheilkunde* (Band x. Heft 1 and 2) is occupied by this valuable paper. Dr. Bókai, who is directing physician to the Children's Hospital at Pesth, has already contributed to the literature of the subject, he having published, in the first volume of the *Fahrbuch*, twelve cases of the affection. His present communication is based upon the observation of 144 cases, in which, for statistical purposes, the first twelve are included. Of the whole number, 129 were idiopathic; three were due to the burrowing of cervical abscesses; four were secondary to vertebral disease; seven occurred in the course of scarlatina, and one was the result of an impacted foreign body—a brooch. Besides these, there were forty-three cases of lymphadenitis retropharyngealis, which terminated in resolution. The idiopathic cases were all believed to have originated in lymphadenitis. A large majority of the abscesses were situated laterally; only one-sixth occupied the middle line.

In the etiology, sex appeared to have no influence except that three out of the four patients, in whom it was secondary to vertebral disease, were boys. By far the larger number (134) occurred under four years of age; thus eighty-six in the first year, thirty-four in the second year, and fourteen in the third year. The youngest patient was eight weeks old. Thirty-two were distinctly scrofulous; ten rachitic. The preponderance of the affection in early childhood is ascribed to the much greater frequency of local affections of the mouth and throat at this period, more especially perhaps in connection with dentition. Scarlatina was not a very potent factor in its production, since only seven out of a total of 664 scarlatina patients were affected by it.

The first symptom of postpharyngeal abscess is difficulty of swallowing (in infants, inability to suck) which may lead to regurgitation, and may be associated with vomiting, of the food. Next, the voice becomes muffled or nasal, or when the abscess is fully developed, of a gurgling character; during sleep the patient snores loudly. The interference with respiration is greatest when the swelling is near the glottis, and, in these cases especially, the child is very restless, and frequently wakes in a choking fit. The position and the extent of the abscess have the most influence upon the respiration; but the small size of the throat in young children, and the possibility of oedema glottidis, must also be taken into consideration. The increased secretion is a further

hindrance. Cough is not constant; and, when present, is usually a late symptom. The neck is stiff and, in the advanced stage, a prominence may be seen near the angle of the jaw; in the earlier stages, this must be felt for. On examining the throat, the isthmus faucium appears narrowed and is covered by an accumulation of viscid mucus. The pharynx and adjacent parts are very red, and a swelling of the same colour, and of the size of a bean or larger, is seen on the posterior wall, usually behind one of the tonsils; the soft palate and uvula are thrust forward. The negative results of inspection are not sufficient to exclude abscess. Digital exploration is the only means of determining with absolute certainty its existence; and this method gives one in addition an idea of its development and of the distance it extends downwards. It must, therefore, never be omitted. Fluctuation may be felt if the lump in the neck be pressed while the finger is on the abscess. Fever, in the beginning, is but slight in acute cases, and is often absent in the chronic and subacute; when the abscess is fully formed it is present, but the temperature is rarely over 103° F., and the pulse is not markedly quickened unless cyanosis sets in.

Of the 144 patients, 120 were cured, 11 died, and 13 were lost sight of. An analysis of the fatal cases gives the following results—five out of the 129 idiopathic cases, three out of the four with vertebral disease, two of the seven scarlatina patients, and the one traumatic case. The three, in whom it was secondary to cervical abscesses, all recovered. In general, it may be affirmed that the termination will be probably fatal unless surgical aid be given. Spontaneous bursting of the abscess must not be waited for, though it occurred in 19 cases. Of the 11 above cited as fatal, seven were opened with the bistoury, two opened spontaneously; and, in two, the abscesses remained unopened. The prognosis is unfavourable when the child is very young or weak, when the course of the disease is very acute, and when the abscess extends very low down. Of the complications, the most important is pneumonia. This occurred in 10 cases; in three before the opening of the abscess, in seven after this; it was engendered apparently in the latter, by the admission of pus into the air-passages. Facial paralysis occurred in three cases, perforation of the external meatus in one.

The treatment of lymphadenitis consists in the application of cold compresses, which, if the case be acute, must be very frequently changed. At the same time, cold is to be applied internally; small pieces of ice may be swallowed, or, in those too young to understand this, iced water may be syringed against the pharynx. As soon as pus forms, poultices or warm compresses must be substituted, and when the abscess is fully developed, it must be opened. In five advanced cases, the pressure of the finger was sufficient for this, and they all ended in recovery; though, in one, the abscess refilled and had to be opened with the knife. The instrument usually employed was an ordinary sharp-pointed light bistoury, guarded or not with strapping; when the abscess was very low down, a curved trocar was used. In some cases, the operation saved the patient from imminent death. The after-treatment consists in syringing out the throat with lukewarm water, and in maintaining the incision patent for some days; the occasional pressure of the finger is generally enough for this. Severe bleeding may follow the operation, especially when this is attempted too early; but, unless an artery be wounded (and the proximity

of the internal carotid must not be forgotten), cold injections should suffice to arrest this. Another danger is the entry of pus into the air-passages; this produced asphyxia in two cases, and would have been fatal but for timely faradisation of the phrenic nerve. The influence of this accident upon the development of pneumonia, has already been referred to. Abscesses in connection with vertebral caries should not be opened unless they offer a serious impediment to respiration or deglutition. In no case was it deemed advisable to open a postpharyngeal abscess from the outside, though it is allowed that such a course may be sometimes necessary. The article closes with the notes of ten cases.

[One cannot but feel some surprise at the large number of cases; but it must be remembered that they were spread over twenty-two years. The total number of patients treated at the hospital during the same period was 109,189. The great length of the paper renders it impossible to do complete justice to it in these columns, so that those specially interested in the subject must be referred to the original.—*Rep.*] RALPH W. LEFTWICH, M.D.

RAYMOND, SOULEZ, AND CHOFFÉ ON HYDROBROMATE OF QUININE.

IN the *Journal de Thérapeutique* for August 25 and September 10 are three articles by Drs. Raymond, Soulez, and Choffé, bearing upon the therapeutic value of the hydrobromate of quinine. The first paper, that by M. Raymond, narrates the experience of the remedy in M. Gubler's service at the Hôpital Beaujon, where several cases of intermittent fever have been successfully treated with it. It is specially to its use in cases of this nature that the present paper is confined, and Dr. Raymond reserves for future consideration its influence in gastric derangements of a remittent form, in acute articular rheumatism, and some other affections.

Five cases of intermittent fever, four being tertian and one quotidian, are narrated, in all of which the remedy seems to have had a very rapid effect in stopping the attacks. In one case the fever had resisted the action of the sulphate of quinine, which though administered only in small doses, caused buzzings in the ears, vertigo, and other symptoms of cinchonism, but quickly disappeared after two injections of 20 centigrammes (3 grains) each of the hydrobromate.

These observations show unmistakably the powerful action of the hydrobromate administered by subcutaneous injection. The cases were all of an exceedingly well marked character; the method of treatment employed consisted in the injection of 10 centigrammes ($1\frac{1}{2}$ grains) of hydrobromate of quinine in solution, twice in the morning and twice in the evening. This treatment produced the following results: in all the cases the intermittent fever was cured; in three very small quantities of the remedy (40 to 80 centigrammes: 6 to 12 grains) sufficed to cut short the attacks and prevent their return; in one case two grammes (30 grains) were required. Two of the patients who left the hospital ten days after the cure had a reaccession of the fever, but on being readmitted to the hospital and again placed under the treatment they were again rapidly cured, and this time definitively.

These facts force upon us the conclusion that intermittent fevers, even when very severe, are easily

cured by subcutaneous injections of hydrobromate of quinine, and very often by very small doses of it. Its rapidity of action is remarkable, and to this rapidity is added certainty. With regard to the local effects of the injection, Dr. Raymond says that in over 300 injections no accident has occurred; very slight local swelling has sometimes been observed, but this has always rapidly disappeared without inflammation.

The hydrobromate has also been employed in febrile gastric derangement, when there was marked access of fever towards evening; in some catarrhal fevers, in acute articular rheumatism, etc., and in all of them good results have been obtained, and the fever has rapidly yielded. It would therefore appear that the sphere of action of the drug is by no means limited to paludal affections, but that it may advantageously take the place of the sulphate of quinine in all cases in which that remedy is indicated.

Dr. Soulez's paper is devoted to a consideration of the precautions necessary to avoid local accidents in hypodermic injection, and of the harmlessness of injections of hydrobromate of quinine.

He has practised injection 116 times, on 32 patients, the subjects of acute attacks of intermittent fever, or of attacks appertaining to that form of special anæmia described under the name of paludal cachexia. In 90 of the cases 10 centigrammes were injected, in 25 of them 20 centigrammes, and in one 30 centigrammes. In the 10 and 20 centigramme doses some very slight pain was caused at the moment when the liquid raised the skin, and in one of the 20 centigramme cases slight inflammation of the dermis was produced. The injection of 30 centigrammes caused an erysipelatous inflammation about a square decimètre ($3\frac{1}{4}$ square inches) in size.

Dr. Soulez proceeds to say that in cases where great alteration in the organism exists, as the result of severe fever, typhoid for example, or where there is prolonged suppuration or pulmonary phthisis in an advanced stage, the practice of injections must be forbidden.

The precautions necessary to be observed in the injection of the hydrobromate are as follows. The passage of the needle through the skin should be as direct as possible; the point of the needle should be carried into the cellular tissue at a certain distance from the point of entry. The injection should be made very slowly, and the finger should rub gently so as to diffuse the liquid; the needle must be withdrawn very gently and slowly; before it leaves the tissues it should be gently raised, and the skin should be pressed by the finger on the cannula, and the finger should remain applied for some seconds. To sum up, it appears that the injection of hydrobromate of quinine in doses of 10 centigrammes is absolutely innocuous to the cellular tissue; and the same will probably be the case with doses of 20 centigrammes, though it will be prudent at present not to go beyond this.

In the paper of Dr. Choffé, the author narrates his experiences with the drug in Algeria, Cochin China, and India. He has employed the drug in four different classes of cases: 1. In paludal fevers; 2. In neuralgia of a similar origin; 3. In internal congestions; 4. As a sedative. He has only employed the salt in the form of pill or solution, and has not administered it hypodermically. In miasmatic fever Dr. Choffé has used the hydrobromate in about thirty cases and has found it superior to

the sulphate in the fact that the dose is smaller, cinchonism absent or very slight, and that vomiting when present has always quickly ceased. In intermittent neuralgia, also, he has found it act much more rapidly than the sulphate, and in some cases it has been effectual where the sulphate had failed. It is, however, above all as a sedative in febrile affections that Dr. Choffé considers the hydrobromate valuable. In hectic fever accompanying phthisis and in articular rheumatism, acute and chronic, he has by its aid procured good nights with sleep. He also employed it in an epidemic of scarlatina with admirable calmative effect.

Dr. Choffé concludes by expressing his opinion that in hydrobromate of quinine the physician has a most valuable remedy, gifted with febrifuge qualities equal to any previously known, and uniting with them a calmative power superior to the sum of the substances composing it.

W. DOUGLAS HEMMING.

ANATOMY AND PHYSIOLOGY.

TSCHIRIEW ON THE DEPENDENCE OF THE RHYTHM OF THE HEART ON VARIATIONS IN THE BLOOD-PRESSURE.—As to immediate effects of the blood-pressure on the rhythm of the heart, the results of previous investigators coincide tolerably well. They all found that, when the blood-pressure was increased, after separation of the heart from the central nervous system, there was either acceleration or slowing of the heart-beats; and less frequently the heart-beats were unchanged. As to the interpretation of these phenomena, however, there is much variance. Nay, Knoll and Navrocki have even denied the 'facts' of previous experimenters.

S. Tschiriew, of St. Petersburg (*Centralblatt für die Medicin. Wissenschaften*, no. 35), has again investigated this subject, and confirms the results of former experimenters (Ludwig, Thiry, Bezold, E. and M. Cyon). He has discovered a new fact, namely, a very considerable and sudden slowness of the heart-beats during the increase of the blood-pressure, as well after section of the cervical nerves alone as after complete separation of the heart from the central nervous system; a subsequent, sometimes very considerable, acceleration of the pulse after the cessation of the increase of blood-pressure, on cessation of the pressure exerted on the abdominal aorta.

The conclusions at which the author arrives are the following. 1. Considerable and rapid variations in the blood-pressure can change the rhythm of the isolated heart. 2. Every considerable and rapid increase of blood-pressure can directly excite both inhibitory and the motor cardiac ganglia, by increasing or diminishing the number of beats, the number seldom remaining the same. 3. The final character of the changes in the hearts' rhythm during the increase of the blood-pressure depends upon the counterbalancing actions of both of the above named factors. For a weak stimulation of the vagus can completely extinguish the phenomenon of a maximal stimulation of the nervous accelerans (Bowditch), so it is easily understood, why 4. in those cases where the inhibitory mechanism of the heart is sufficiently developed and excitable, the increase of the blood-pressure for the most part slows the heart's rhythm, whereby the accumulated excitation of the motor ganglia appears after the cessation of

the increase of pressure, *i.e.* as subsequent acceleration. If, on the contrary, the inhibitory apparatus be feebly developed and exhausted by previous stimulation, then a very considerable increase of the pulse-beats may occur during the increased blood-pressure. 5. The more pronounced the acceleration of the heart-beats during the increase of pressure, the feebler is the subsequent accelerating effect, and *vice versa*. 6. The heart receives from the accelerating nervous system a constant tonic excitation. The central ends of this system can be excited by increase of the blood-pressure but not by its diminution. In the normal condition, in addition to this direct influence, there is an indirect one; through the vagi and accelerantes. 7. Small doses of atropin paralyse the peripheral ends of the vagi (a fact already well known), but not the inhibitory apparatus itself. 9. The pulsus bigeminus is simply a slow pulse, in which the ventricle is peristaltically contracted. 9. Anacrotism of the pulse, as is the case in aortic insufficiency, or in the arterial stenosis, is the expression of peristaltic heart contractions, and not of variations in the elasticity of the wall of the vessel.

RANVIER ON T-SHAPED NERVE-TUBES AND THEIR RELATIONS TO GANGLIONIC CELLS.—L. Ranvier (*Comptes Rendus*, December 30, 1875, and *Centralblatt für die Medicinischen Wissenschaften*, no. 30), investigated the spinal ganglia and the ganglion Gasserii of rabbits by the interstitial injection of perosmic acid, and agrees with former authors that the cells are unipolar. Whilst former authors imagined that the fibres springing from the cells, passed either towards the centre or the periphery, Ranvier is convinced that these fibres, after a longer or shorter twisted course, are inserted in a T-shaped manner into one of the nerve-fibres of the posterior root, and becomes united to it. This insertion always takes place at a Ranvier's node.

The author does not affirm that the processes of unipolar cells all end in this way. Still, he remarks that, on teasing the posterior root just at the spinal ganglion, an extremely large number of T-shaped nerve-fibres are to be found. The author also remarks on the possibility that the processes of the unipolar ganglionic cells may not be inserted singly on to single nerve-fibres, but that several of them may perhaps unite in a common trunk, which becomes inserted in a T-form on a fibre.

WM. STIRLING, D.Sc., M.D.

RUTHERFORD ON THE ACTION OF THE INTERCOSTAL MUSCLES.—Professor Rutherford, being convinced that Hamberger's model of the action of the intercostal muscles by means of parallel bars and elastic bands is erroneous in principle, adopts the less fallacious method of applying the elastic bands by means of nails to the ribs themselves of a skeleton; for, as Professor Humphry has demonstrated, the ribs, unlike the rigid bars of the above-mentioned model, are arcs capable of rotation round an axis directed from their posterior ends to the costal cartilages. The results of Professor Rutherford's experiments are recorded in a short note, illustrated by figures taken from photographs, in vol. x., part iii. (April, 1876), of the *Journal of Anatomy and Physiology*.

In the model the representation of the ribs descend by the action of the elastic bands; but in the skeleton the ribs are raised—the second, third, and fourth individually, their costal cartilages being separate,

while, if the fourth and fifth ribs be further connected by a band, a simultaneous elevation of the latter and of the four succeeding ribs will result, owing to the fusion of their cartilages. Since the first rib is more fixed, being unlike the rest, less flexible, devoid of joint between it and its cartilage, and forming an arc of a smaller circle, the ribs which succeed it are raised; but if the last rib of the series be made the fixed point, by being held immobile, all those above it [the first rib excepted? *Rep.*] will be, on the contrary, depressed. Both the external, as well as the internal intercostals, seem to elevate the ribs to which they are attached, though it would appear that, by the action of the former, the *manubrium sterni* is more elevated, and the ensiform process drawn further forward than they would be by the latter series of muscles. How far this experiment may indicate the powers of the actual muscles it is impossible to say, as the effect of the elastic bands depends, not only on their position, but also on the degree of their power of stretching.

JOHN C. GALTON.

EWART AND THIN ON THE STRUCTURE OF THE RETINA.—J. C. Ewart and G. Thin give an abstract of their researches on this subject (*Journal of Anatomy and Physiology*, vol. xi. part i. pp. 96-108). They find, in the first place, that the true radial fibres of the frog's retina extend beyond the external limiting membrane to the outer segments of the rods. Taking the layers *seriatim* from within outwards, the chief points observed by them are as follows.

Membrana limitans interna.—This is described as distinct from the hyaloid, and covered with epithelial cells. In the sheep a double layer of cells was observed, which can be distinguished from the ends of the radial fibres immediately external to them.

Optic Nerve-Fibres.—In what were probably delicate fibrillary bundles of connective tissue in this layer, the authors observed many narrow elongated cells, but are unable to say whether they completely invest the bundles or not.

Ganglionic Cell-Layer.—The authors have nothing new to add with regard to this layer.

Molecular Layer.—On both surfaces of this the authors found a layer of small round nucleated cells, investing it like an epithelium. The ground substance of the layer they found to consist of parallel cylindrical elements of uniform size, with a diameter equal to that of a human blood-corpuscle. Lying on these cylinders were cellular elements, either cells or cell-nuclei. In vertical sections of the frog's retina they found a division into seven or eight layers separated by clear spaces.

Internal Granule Layer.—This the authors describe as composed of small rounded cells, arranged like an epithelium; of radial fibres with their nuclei; of small spindle-cells and of narrow flat cells, sometimes adhering to the membranous substance connecting the radial fibres. They are unable to distinguish the bipolar ganglionic cells of Schultze and Schwalbe.

Intergranule Layer.—This the authors believe to consist, in the frog, of two cellular membranes bounding the granule layers. They have also found in this layer numerous delicate true fibres continuous, many of them with the radial fibres.

External Granule Layer.—The authors describe as outer and inner pedicles of the rods conical bodies united by their apices, the former being separated

from a rod by a narrow line. Between these are elliptical bodies, which they term pedicles of the cones. Rounded nuclei are seen in the frog's retina, belonging to cells which lie in two rows between the external limiting membrane and the intergranule layer. Elliptical nuclei also occur appertaining to cells arranged in a similar manner. All fibres of this layer they describe as belonging to the system of radial fibres. They have observed them uniting after passing through the layer or bifurcating after piercing the external limiting membrane. There is, however, no actual continuity between them and the rods and cones.

External Limiting Membrane.—Besides fibres resembling radial fibres and true membranous substance, the authors find a continuous layer of cells, which in teased preparations may be seen attached to the inner segments of the rods and cones. There is no continuity between the inner segments of the rods and cones and their corresponding pedicles (Körner), the above cells separating the two completely.

Bacillary Layer.—In the frog's retina the authors describe between the two segments of a rod, and completely separating the one from the other, a round nucleated cell which can be distinguished from the lens-shaped body (*linsenförmige Körper*) of Max Schultze. The authors have observed long narrow cells lying on the inner segments of the rods, and nuclei on their outer segments. The latter, they think, are probably ensheathed by a membrane. They have not seen any axial thread in the outer segments of the rods.

Pigment-Epithelium.—In opposition to previous observers, they conclude that the pigment of the retina is always external to the substance of the cell, and is therefore contained between, and not within, formed elements. In conclusion, the authors have found no proof of the nervous nature of the rods and cones, and were unable to trace the nerve-fibres from the ganglionic cells further than the molecular layer.

It is to be regretted that from want of space the authors are unable to give an account of the methods employed in this research.

VINES ON THE DIGESTIVE FERMENT OF NEPENTHES.—Mr. Sydney H. Vines (*Journal of Anat. and Phys.*, vol. xi. part i. pp. 124-27) gives the results of his experiments on the digestive process in 'carnivorous' plants. He finds that they are capable of digesting proteid matters by a process essentially similar to that by which the gastric digestion of animals is performed, and that, in the second place, the mode of origin of the digestive ferment, in *Nepenthes* at least, is essentially similar to that indicated by Heidenhain with reference to the digestive ferment of the pancreas (pancreatin), and by Ebstein and Grützner as regards that of the stomach (pepsin). He has also experimented with the pitchers of *Sarcenia* (*flava*), but has as yet failed to ascertain the presence of a digestive ferment in them.

LANGLEY ON THE ACTION OF PILOCARPIN ON THE SUBMAXILLARY GLAND OF THE DOG.—Mr. J. N. Langley describes (*Journal of Anat. and Phys.*, vol. xi. part i. pp. 173-80) the results of his experiments on this subject, in which a solution of nitrate of pilocarpin (the alkaloid of *jaborandi*) was injected into the saphena vein or the facial artery. He sums up the action of this substance as follows.

In small doses (up to about 30 milligrammes) it exerts an action on the gland very similar to that produced by stimulation of the chorda tympani. It causes a rapid secretion and a considerable increase of blood-flow, both of which gradually decline. Its effects are little if at all altered by section of chorda tympani, or of the sympathetic. Stimulation of the chorda tympani increases the effects of the pilocarpin; stimulation of the sympathetic on the other hand diminishes the effects, so that both nerves are functionally unaltered. The secretion is stopped by injecting atropia, but a quantity sufficient to paralyse the chorda tympani does not prevent a relatively large quantity of pilocarpin from producing its ordinary results. The secretion or absence of secretion is dependent on the relative quantity of the two poisons present, as is the standstill or beat of the heart.

In larger doses, it causes no flow of saliva at all, and prevents the chorda tympani from producing any secretion. It considerably diminishes the blood-flow through the gland, as well as the effect of the chorda tympani on the blood-flow. It does not, however, stop the sympathetic secretion.

DRESCHFELD ON A NEW STAINING FLUID.—Dr. J. Dreschfeld (*Journal of Anat. and Phys.* vol. xi. part i. p. 181) draws attention to a dilute solution of eosin (1 part to 1,000-1,200 parts of water) as a microscopic staining fluid. The sections to be stained, having been immersed in this fluid for one minute to a minute and a half, are put for a very short time into water slightly acidulated with acetic acid, and can then be mounted in glycerine or in Canada balsam. The advantages claimed for this fluid by the author are these. 1. The time required for perfect staining does not exceed one to one-and-a-half minute. 2. The solution can be kept without altering, and remains perfectly clear for any length of time. 3. Eosin has the property (probably owing to its fluorescence) of clearing tissues. 4. It differentiates the component parts of a tissue, which renders it particularly applicable to complicated structures, as tumours.

The author finds it particularly useful in the examination of nervous tissue. The nuclei, nucleoli, and processes of the ganglion-cells, and the axis-cylinder of nerve-fibres, are stained light pink; the areolar tissue takes a much deeper colour; the medulla of the nerve-fibres, on the other hand, is not stained at all.

CREIGHTON ON THE DEVELOPMENT OF THE MAMMA AND OF THE MAMMARY FUNCTION.—Dr. C. Creighton (*Journal of Anatomy and Physiology*, vol. xi. part i. pp. 1-32) combats the generally accepted opinion that the mamma is a complex extension inwards of the ectoderm, and confirms, to a great extent, the views expressed by Goodsir, with regard to the development of glands in general, and their growth during a period of functional activity. The agreement, however, of his conclusions with those of Goodsir was not known to the author, till his own were in great part formed. The author describes the development of the mammary acini in the guinea-pig, and that of the inguinal fat body of the kitten, and traces the striking resemblance existing between the two processes: he then describes the development of the ducts in the guinea-pig. His conclusions are these. 1. The mammary acini of the guinea-pig develop at many separate points ('ger-

minial spots' of Goodsir) in a matrix tissue; the embryonic cells from which they develop are of the same kind that give origin to the surrounding fat tissue; and the process of development of the mammary acini is, step for step, the same as that of the fat lobules. 2. The ducts of the mamma develop from the same matrix tissue by direct aggregation of the embryonic cells along predetermined lines; the ducts develop in the individual guinea-pig before the acini, whereas in the phylo-genetic succession the ducts are a later acquisition; and this reversal of the order of acquisition of parts is in accordance with the principle stated by Mr. Herbert Spencer that, under certain circumstances, the direct mode of development tends to be substituted for the indirect.

The homologue of the mamma is therefore, according to the author, not a recess of the ectoderm, but a fat-body. In a previous paper the author has described the cellular changes occurring during each 'evolution' of the gland in pregnancy, and he concludes that these are simply a repetition of those cellular changes which the cells of the part went through in their development. The function of the mamma may therefore be said to be a sustained repetition of its development.

E. CRESSWELL BABER, M.B.

PATHOLOGY.

MATTERSTOCK ON THE BLOOD IN ACUTE YELLOW ATROPHY OF THE LIVER.—Matterstock (*Wiener Med. Wochenschrift*, 1876, pp. 882 and 910) has made observations upon the blood of two cases of acute yellow atrophy of the liver which were under the care of Professor Gerhardt in the Julius Hospital at Würzburg.

The blood was obtained in the usual way by pricking the finger; a drop was immediately put upon a glass slide, and forthwith examined with the microscope. In the first case, a great increase in number of the white corpuscles was seen, approaching 1 to 12. In the second, the white corpuscles were also somewhat increased, but the chief changes were seen in the red corpuscles. Not one could be found with the natural aspect. Two shapes prevailed: one, the mulberry; the other the stellate. [It will be thus seen that one shape is only an exaggerated state of the other, the processes from the corpuscles being in one case rounded, in the other pointed.—*Rep.*] Four to eighteen of these processes were seen at the border of a corpuscle; no movement or cleavage of the corpuscles could be made out.

The corpuscles themselves were dotted with points, according to the number of the processes. The corpuscles which showed no processes looked swollen and pale, as if acted on by water.

By the side of these changes appeared those which always take place when blood is drawn from the vessels, and which are commonly set down to dilution with water or cooling of the blood (Rollett). These corpuscles appeared smaller than the rest, contracted and with processes much less marked than in comparison with the others. These either fell together in groups or showed singly in the field in the midst of the large corpuscles.

In the first case the same appearances were seen, but the corpuscles were not altered in such large

numbers. Some had curved themselves into the shape of a saddle. The cupping of the disc could well be made out.

Matterstock thinks these changes not due simply to the removal of the blood from the vessels; but at the same time does not insist that these altered shapes circulate in the blood. He next inquires by what agents these changes are caused. It is not due to the high temperature of the blood, as that never rose above 38.5°C. or 101.3°F. Neither is it due to the bile-acids; as they have quite a different action on the corpuscles, suddenly and completely destroying them. In uraemia the blood-corpuscles are quite natural in shape. In conclusion, Matterstock remarks that there are many points in common between the appearances seen in these corpuscles and in the monad-containing corpuscles described by Hüter. They differ, however, as the corpuscles from the jaundiced patients showed no to and fro movement.

J. WICKHAM LEGG, M.D.

MAZZOTTI ON A CASE OF NUMEROUS CYSTICERCII OF THE BRAIN AND CEREBRAL MENINGES. Dr. Luigi Mazzotti describes in the *Rivista Clinica*, 1876, the case of a woman, aged thirty-two, who, having previously had no illness of importance, had, after a natural labour in June 1874, abundant metrorrhagia, which was treated by repeated cold applications to the abdomen. Early in August she began to show symptoms of mental disturbance, consisting chiefly in hallucinations of sight. Afterwards, she had convulsive attacks, but preceded by premonitory symptoms; these were of short duration, and left the patient extremely exhausted and weak. Her moral character was changed; she became somewhat irritable, and her intellect and memory were observed to be weakened. These symptoms having continued several months, in May 1875 she was seized with violent pains in the head, affecting first the vertex, then the nape of the neck. As there was no improvement, she was admitted into the hospital at Bologna on July 23, 1875.

On admission, she appeared to be well fairly nourished and florid; there was nothing abnormal in the form or size of the head, nor any appreciable lesion of any other part of the body; her senses were perfect; the pulse and temperature normal. She answered questions correctly, though rather slowly; and herself acknowledged that her ideas were rather confused and her memory weak. Her speech was slow and in cadence, but accurate and free from stuttering. She preserved her appetite well, and her digestion was good. She had pain all over the head, but it was most severe at the nape of the neck. The paroxysm of pain came on at all times of the day and night without apparent cause, and were only temporarily relieved by hypodermic injections of acetate of morphia and by the internal use of choral.

On the second day from her admission into hospital, she had a convulsive attack attended with foaming at the mouth and loss of consciousness. She had no more attacks of the kind; and on August 2 she died suddenly. On *post mortem* examination, the dura mater, on both the vault and base of the skull, was found studded with numerous cysticerci; the arachnoid and pia mater were much congested, and adherent. The brain was literally occupied with cysticerci; they were found in both peripheral and the central parts, in the upper part and in the base, in the white substance, grey substance, and great ganglia. None were found in the

cerebellum, medulla oblongata, eye, or muscles, nor in any other part of the body. The thoracic and abdominal viscera were healthy, except that the lungs presented old deep cicatrices at their apices.

A. HENRY, M.D.

ROKITANSKY ON MALFORMATIONS OF THE CARDIAC SEPTA.—In the July number of the *Journal of Anatomy and Physiology*, appears a translation of an analysis by Professor Stricker, of Vienna, of an exhaustive monograph by the veteran pathologist, Professor Rokitansky, entitled 'Die Defecte der Scheidewände des Herzens.' Anyone who has been fortunate enough to study in the Pathological Institute attached to the General Hospital in Vienna, will readily understand from what wealth of material, not to speak of the accumulated observation of a long and busy lifetime, the learned professor has been enabled to draw. A but little known dissertation by Lindes (Dorpat, 1856) is, it seems, the only work in which similar statements as to the development of the heart, differing from such as are in general acceptance, are to be found.

The septum auricularum does not, as hitherto received, develop upwards, sickle-wise, so that a foramen ovale is left, but, beginning at the roof of the as yet simple auricle, extends thence forwards along the anterior and posterior walls. A stage, however, is reached in the course of this development, in which the septum may be represented as a curtain stretched between the upper end of the vertical ridges. In the lower half of this partition there is, at first, at all events, a foramen by which the two auricular cavities communicate; but by the forward growth of the septum this aperture is gradually closed up, so that each cavity comes to be shut off from its fellow. Before however, the septum has become fused by its lower border with the roof of the ventricles, certain small apertures may be seen in it, in the chick, *e.g.* about the fourth day of incubation, which increase in number until about the sixth day of incubation; this curtain comes to resemble a beautiful lattice. Through this the blood-stream is filtered from right to left, causing it to bulge, pouch-like, to the latter side. The meshes are gradually closed up, until at last but one fissure-like aperture, the foramen ovale, is left at the upper anterior border of the septum. In a human foetus, of three months, the septum auricularum took the form of a membrane perforated sieve-wise, and supported upon a muscular frame, while at five months it had the appearance of knitted work, *i.e.* seemed to be extremely thin at numerous points, as though here perforated. This appearance, together with a bulge towards the left, was witnessed in foetuses of seven and eight months, and even in the newly born. Peacock ascribed a persistence of the embryonal lattice in the heart of the new-born child to a premature closure of the foramen ovale.

It is worth recording that in the foetus of a horse this structure was seen to resemble a pouch, with perforations near its front border, supported upon a muscular frame, and bulging into the left auricle, thus closely resembling its homologue in man and in the bird. It is owing, moreover, to the septum auricularum that there is to be seen, even from the very beginning, a prominence lying above and behind in the vena cava, in such wise that a small portion of this vessel to the left is parted off as a *cul de sac*, open toward the left auricle, and originating the pulmonary veins.

The ventricular septum begins as a crescentic muscular ridge, with its convexity pointing upwards, inserted into the anterior, inferior, and posterior walls of the single ventricle, a foramen being thus left at its upper border, so that there is a stage in development in which the two cardiac septa together form a partition perforated by a figure-of-8 foramen. Of this the upper half is eventually filled up, as already stated, while the lower remains always patent, as the ostium aorticum.

As regards the bulbus arteriosus, this originally opens entirely into the right ventricle, then becomes divided by a special septum into an anterior pulmonary artery and a posterior aorta; at which stage both large arterial trunks belong to the right ventricle, while the left ventricle would be quite devoid of exit did not the foramen septi ventriculorum remain permanently patent. At a certain stage in development the left ventricle pours its blood into the right, whence mixed blood passes into both pulmonary artery and aorta. Afterwards the circumference of the foramen just mentioned grows gradually on the side facing the right ventricle, so that the aorta may be said actually to grow through the right ventricle. It will be readily understood, after the statement that the ventricular septum is divided into a posterior membranous and anterior muscular portion, this latter being further separable into a posterior and anterior part, that a deficiency of the posterior part of the muscular portion leads to an intercommunication between the two ventricles, while incompleteness of the anterior part causes a communication between the two large arterial trunks.

Malformations of the auricular septum may be divided into two distinct groups; the first including those determined by the development of the primary or provisional system, this being either entirely or partially wanting, *e.g.* below, having failed to reach to the septum ventriculorum, while the second group includes all defects arising during the transformation of the primary into the secondary septum, *e.g.* the vessels in the latter do not come to be filled up. After what has been already stated, it will readily be understood how a stenosis of the aorta must cause the blood of the left ventricle to accumulate to an excessive amount in the right ventricle, since both this vessel and the pulmonary artery originally open into the latter cavity. This repletion of the right ventricle must cause the corresponding auricle to become overfilled, and consequently bring about an enlargement of the interauricular foramen. If, however, development have proceeded as far as closure of the interventricular septum and consequent limitation of the aorta on the side of the right ventricle, the excessive distention with blood will be confined to the cavities of the left heart, those on the right side being only secondarily affected through the pulmonary circulation. When a deficiency, either partial or complete, of the septum ventriculorum is accompanied by a similar condition of the interauricular septum, an instance is here seen of a bilocular heart—a fish-like character; while, if the latter septum alone be fully developed, an example of a trilocular organ—reptilian in character—is afforded. Anomalies in position of the large arterial trunks are invariable sequelæ of a complete absence of the interventricular septum.

With regard to stenosis and atresia of the pulmonary artery, Professor Rokitansky divides them into three groups, and combats the view hitherto

taken that they are due to inflammation occurring in the foetal heart ; proving instead that they are rather malformations due to various degrees of arrest of development, which may later be modified by some inflammatory process. As for atresia of the pulmonary artery, this occurs whenever the deviation of the septum of the bulbus arteriosus, already described, from the normal arrangement is so considerable that this partition, the convexity of which is directed towards the pulmonary artery, becomes actually applied to the wall of that vessel, and fuses with it as far down as its mouth.

JOHN C. GALTON.

BROWN-SÉQUARD ON ALTERATIONS IN THE MUCOUS MEMBRANE OF THE STOMACH CONSEQUENT ON LESIONS OF THE BRAIN.—Dr. Brown-Séquard (*Progrès Médical*, 1876, no. 8), records that, after injuries of the corpus striatum, crus cerebri, or spinal cord, softening and ulceration of the gastric mucous membrane occur ; hæmorrhage generally after injury of a certain part of the pons Varolii. There is no hæmorrhage after paralysis of the vaso-motor nerves ; on the contrary, the arteries and veins contract, and the blood stagnates in the capillaries, which then rupture.

GENERSICH ON THE PACINIAN BODIES FOUND IN THE HUMAN COELIAC PLEXUS.—A. Genersich (*Wiener Medicinische Jahrbuch*, 1876, p. 133) investigated the Pacinian bodies occurring in the coeliac plexus in the bodies of 82 individuals who died of different diseases. He found these bodies in 73 cases, their number and size being independent of sex and the disease. The size, on the contrary, had a nearly constant relation to the age of the individual. In children, and in youth, their length was about 1 to 1·5 millimètres, their breadth 0·5 to 1·0 millimètres, in more advanced life they were somewhat larger ; the largest, 3·6 millimètres long, and 2·3 millimètres broad, were found in patients over fifty. The description coincides exactly with that given by Axel Key and Retzius. The very large forms found in old individuals are produced by œdematous swelling. As the cause of this œdema, occurring independently of general dropsical swelling, the author assumes a local origin. According to him a fibrous thickening of the capsule takes place, which interferes with the return of the blood and lymph, and so produces the œdema of these small organs. As this fibrous thickening occurs especially in old age, it explains the increase in size observed to take place at this period.

In one case calcification of the artery of the pedicle had occurred without any obvious change of the terminations of the nerves ; in another case, both the stem and the interior of the Pacinian corpuscle had undergone fatty degeneration.

PAOLUCCI ON A CASE OF EPIDEMIC CEREBRO-SPINAL MENINGITIS WITHOUT SYMPTOMS.—Dr. Gaetano Paolucci relates in *Il Morgagni* for May the case of a young man, aged twenty-one, who had previously suffered from cutaneous eruptions, oœna, articular rheumatism, frequent epistaxis, and latterly from precordial pain with fever. He was admitted to hospital on the fifth day of his illness, having presented subjective symptoms of pneumonia of the left lung ; and, on physical examination, lobar pneumonia of the base of that lung was found. The area of cardiac dullness was increased, more in the longitudinal direction ; the sound over the bicuspid valves was very weak, that over the sigmoid valves was accentuated, and friction-sound was heard. The spleen and liver were enlarged. The pulse was frequent and small ; the strength was much reduced ; there was severe pain at the lower part of the chest on the left side, increased by pressure, by coughing, and by deep inspiration. The temperature, which was high, fell on the tenth day, but suddenly rose again with equal intensity. The patient died on the tenth day after admission.

At the necropsy, pneumonia, pleurisy, and dilatation of the heart were found. But, besides all this, there was the most classical form of epidemic cerebro-spinal meningitis ; the pia mater of the whole brain, especially at the convexity, was strongly congested, thickened, and covered with a fibrino-purulent exudation of greenish-yellow colour, filling the subarachnoid space. These appearances, less in degree, were observed also in the internal aspect of the cerebral hemispheres, on the upper surface of the cerebellum, on the medulla oblongata, and the upper part of the spinal cord. They were found of slight intensity in the cervical portion of the cord, but became more distinct in the dorsal and lumbar regions, and were most intense in the cauda equina, where a large collection of fibrino-purulent fluid was found between the arachnoid and pia mater. There was some exudation along the choroid plexus in the lateral and third ventricles of the brain.

Here was a case of extensive meningitis without symptoms, with no obscuration of consciousness, no intense headache, no jactitation, no muscular contractions or paralysis, no painful sensation in the extremities, no cutaneous hyperæsthesia or anæsthesia, no disturbance of the special senses. There had been vomiting—not spontaneous, however, but when the patient took turpentine.

In attempting to explain this case, two hypotheses may be put forth ; either there was congenital atrophy of the brain, allowing the exudation to take the place of the serum without producing symptoms, or the cerebro-spinal meningitis had already run its course when the patient was admitted, the exudation alone remaining.

A. HENRY, M.D.

COLLINS ON PERFORATING ULCER OF THE DUODENUM.—Dr. Daniel F. Collins relates (*New York Medical Record*, October 9), the case of Jacob

Wenzel, aged thirty years, of low stature, and stoutly made, who, while working in a factory, was hurt by the falling of a piece of lumber. He was confined to his bed for one week with pains in his stomach, hips, and chest, from which, he said, he completely recovered.

On June 20, 1874, about one year from the date of the above occurrence, he was suddenly attacked, while at work, with pain in his stomach, vomiting, and weakness. On June 23, Dr. Collins was called to see him in haste. On arriving at his house he was found sitting up in a chair, breathing with difficulty; face pale; skin of a dirty yellow colour, and quite cold and clammy to the touch. Pulse 60, and very weak. He was vomiting every few minutes, and could not retain even a spoonful of cold water on his stomach. On examination, the abdomen was found to be very much distended and hard, and on pressure being made he complained of great pain over his stomach. He stated that his bowels had not moved for four days, although he had taken medicine.

After ordering some medicine to check the pain and vomiting, and an injection to relieve his bowels, Dr. Collins cautioned him against taking large drinks of ice-water and milk, which he had been doing all day; being unable to retain anything on his stomach, the vomiting caused by these drinks very much increased his suffering and danger. Next day he got out of bed about six o'clock in the morning, walked across his room and drank nearly a pint of iced milk, and in returning back to bed fell on the floor and expired in a few seconds.

At a *post mortem* examination, nine hours after death, about three inches below the pylorus, on the anterior surface of the duodenum, there was found a perforation half an inch long by one-eighth of an inch wide. The edges of this perforation were even, and presented but a slight trace of inflammatory action; the appearance of the intestine around the perforation was natural. The intestines contained a quantity of fetid fluid.

THOMAS ON TEMPERATURE IN TETANUS.—Dr. Thomas, in his *Thèse de Paris*, 1876, relies on the researches made some time since, and as the conclusion of an excellent monograph, formulates his 'considerations on temperature in tetanus,' which he supports by fourteen cases which have come under his observation. He has thence been able to remark that there is always elevation of temperature either at the beginning or the end. Hence he formulates the conclusion that elevation of temperature in tetanus is constant. But according to the analysis of the cases it has been impossible to assign a cause for the elevation of temperature in cases of spontaneous tetanus. This elevation of temperature in traumatic cases may be due to an intercurrent disease or to a traumatic complication. In the great majority of cases followed by death, the notable elevation of the temperature during the last moments in tetanic patients is due to the development of an important pulmonary lesion. It is indeed impossible in the present state of science to recognise any one cause for the elevation of temperature in tetanic patients.

DISEASES OF CHILDREN.

SIMON ON IODINE AND ITS PREPARATIONS IN THE THERAPEUTICS OF INFANCY.—In an exhaustive clinical lecture on this subject, delivered at the Paris Hospital for Children (*Moniteur Thérapeutique*, August 7), M. Jules Simon lays particular stress on the following points. Tincture of iodine should not be applied pure in tubercular children; it should be diluted either with glycerine or with some unguent. Neither iodide of potassium nor iodide of iron should be given to children under two years of age, except perhaps in cases of acute hereditary syphilis, where small doses may be administered. It may be given to the nurse, if the child have not been weaned. Older children bear the drug well. Those who are especially benefited by it are patients robust in appearance, but with soft inelastic flesh and with manifestations of incipient scrofula. Iodoform is of great service in cases of ozena and scrofulous wounds. Albuminuria has been observed by M. Simon in a large number of cases to follow paintings of the surface with tincture of iodine, especially when applied to eruptions. Iodide of potassium produced the same result, but in a smaller degree. On this head, further investigations are promised.

LÖWENSTAMM ON A CASE OF POSTPHARYNGEAL ABSCESS.—In the *Medicinisch-Chirurgisches Centralblatt*, no. 35, Dr. Löwenstamm describes a case in a boy aged three years, previously quite healthy. For a week before he was seen, he had been feverish and had had difficulty in swallowing and in breathing. Rude attempts had been made to raise what was looked upon as a displaced tonsil. The child was pale, the mouth wide open, the head retracted, and the breathing difficult and snoring. A deeply seated swelling was seen behind the left angle of the jaw. On examining the throat, the

posterior wall of the pharynx showed a prominence which, towards the left side, had a yellowish colour; fluctuation was distinct at this part. The cervical glands and the vertebræ appeared quite healthy. The parents, at first, refused consent to an operation, and it was not until the child was in imminent danger of suffocation that this was undertaken. An incision was made and the flow of pus accelerated by pressure upon the swelling in the neck; afterwards the throat was syringed with lukewarm water. Recovery was complete.

BOUCHUT ON MULTIPLE ABSCESSSES OF THE CELLULAR TISSUE IN INFANTS.—M. Bouchut (*Gazette des Hôpitaux*, August 1, 1876), after remarking upon the rarity of this affection, points out that the abscesses may be produced under the influence of three diatheses; the scrofulous, the syphilitic, and 'the puerperal.' In the puerperal form, nodules develop under the skin, which then reddens and becomes thinner and painful. The nodules, at first hard, rapidly soften, and fluctuate, and, finally, unless previously incised, burst. Suppuration takes place much more quickly in this than in the other two forms. In the syphilitic variety, the child has usually already been cured of the commoner manifestations of syphilis, small, hard, slightly movable, nodules (gummata) then appear in the subcutaneous tissue. They pass through the same stages as those of the preceding form, but do not burst for perhaps two or three months. After the discharge of the pus, which is small in quantity and of a yellowish sanious character, the opening remains livid and fistulous for some time prior to closing. If the abscess be situated over a bone, the periosteum is destroyed and the bone exfoliates. The scrofulous form generally occurs between the eighth and the fifteenth year. It is very rarely seen in the first year of life. It begins with very small subcutaneous nodules scattered over the trunk and limbs and less commonly over the face. After having remained stationary for some time, they increase in volume, soften, fluctuate, and break, with a discharge of thick greenish pus. A fistula results, and this, with its reddish livid orifice remains open for several months and leaves a depressed scar, which for a long time is coloured. The treatment of the puerperal form consists in the removal of the child from the mother, the application of linseed poultices, and, as soon as fluctuation is felt, the incision of the lumps. The syphilitic and scrofulous forms should be treated respectively with iodide of potassium and cod-liver oil, etc.; and, while the nodules are hard, iodide of lead ointment should be applied. Four cases are appended.

LÖWENSTAMM ON CHLORAL IN INFANTILE CONVULSIONS.—Löwenstamm (*Medicinisch-Chirurgisches Centralblatt*, no. 35, 1876) speaks of numerous instances in which he has tested the efficacy of this drug in convulsions; and he gives one case in detail. The patient was the third child of a highly nervous woman, who had lost her first and second children from this affection at about the same age as that at which this one was attacked. At the thirteenth day, twitchings of the eyelids and of the angles of the mouth were first observed; these rapidly developed into more general convulsions, which were repeated, later, every ten minutes. The infant was first seen on the sixteenth day of life. He showed then strong twitchings of the face, trismus, clonic spasms of the

limbs, spastic contractions of the thumbs, and contracted pupils; the fit terminated, at the end of five minutes, in profuse perspiration. Two grains of chloral-hydrate were given every hour. The convulsions diminished in frequency and intensity, and, on the following day, he was free from them. As the case was considered to depend upon dyspepsia, an antacid in the form of *magnesia usta* was then given, and no recurrence took place.

LEDERER ON FIRST DENTITION IN ITS CAUSAL RELATION TO DISEASE.—Dr. Lederer points out in this paper (*Allgemeine Wiener Medicinische Zeitung*, May 2 and 9) the slender grounds upon which many disorders of childhood are attributed to dentition. He remarks that the most powerful factor in the retardation of the teeth is rickets, and that it is precisely in rickety children that these disorders—bronchial and intestinal catarrh, laryngismus stridulus, convulsions, etc.—are most frequent. During his five years' connection with the Vienna Children's Hospital, he noted ninety-six cases of laryngismus, and of these, ninety-two were in rickety subjects. He further quotes Luzinsky as having observed 504 cases of pulmonary and intestinal affections in rachitic children who showed no sign of teeth. Dentition, moreover, gives no causal indication for treatment; the conditions are far more effectually dealt with according to general rules. The theory is, therefore, useless; but it is even worse than useless, because it frequently leads mothers to defer applying for medical assistance until the case is too far gone, and it engenders in others a carelessness which is most prejudicial to the patient's welfare. Dr. Lederer, therefore, without denying its occasional importance, believes that it is rarely anything more than an exciting cause, which, without special predisposing influence, would be powerless.

RALPH W. LEFTWICH, M.D.

ARCHAMBAULT ON THE TREATMENT OF UMBILICAL HERNIA IN CHILDREN.—In the *Paris Médical*, October 12, is a description of M. Archambault's treatment of umbilical hernia in children. In order to avoid the inconvenience of bandages with buttons, etc., so difficult to keep in their place, M. Archambault takes a piece of white wax, which he softens and rolls between his fingers; this ball is then split in two, so as to constitute two hemispheres. One of these hemispheres, of a size proportionate to the extent of the umbilical depression, is placed with its convex surface in the depression and maintained there by a piece of strapping. For the wax may be substituted gutta percha previously moistened in warm water. At the end of two hours the body will be sufficiently softened to adhere to the skin. From this time no bandage will be required. In this manner M. Archambault has cured umbilical hernia in less than two months.

SURGERY.

BERGER ON ACUTE THYROIDITIS.—The following case is reported in *La France Médicale*, no. 66, 1876. On August 4, 1876, a man, aged forty-six years, was admitted into the Hôpital de la Pitié under the care of Professor Verneuil, with phlegmonous swelling of the whole of the subhyoid region, accompanied by severe constitutional reaction. The affection commenced on the morning of August 1, when the patient, immediately after an attack of hæmoptysis, felt deep-seated pain in front of the neck, which pain was increased by movements of deglutition, and associated with marked dysphagia. The swelling increased rapidly in the course of the day, and became very tender. In the evening, respiration was much impeded, and there was intense fever, accompanied by congestion of the face and violent pulsation of the temporal arteries. These symptoms increased in severity during the three following days. At the time of the patient's admission, the congested face was bent forwards through the action of the sterno-mastoid muscles. There was enormous swelling of the whole pre-tracheal region; the tense skin presented an erysipelatous redness, and the affected region was very tender. On digital examination, a hard deep-seated tumour could be felt, over which the inflamed and oedematous integument could be moved. This tumour seemed to pass under the sterno-mastoid muscles and downwards behind the sternum. The neck could not be moved by the patient, and communicated movements were much restricted and caused intense pain. The respiration was interfered with, and deglutition rendered very difficult. In establishing a diagnosis in this case, glandular inflammation was at once excluded, as such an origin was contraindicated by the extent of the affection, by its commencement in the median portion of the neck, by its diffusion, by the absence of any starting-point of adenitis, and by the acute course of the inflammation. There remained, however, much doubt as to whether the case were one of extensive phlegmon or of acute thyroiditis. In order to remove this doubt, attention was directed in the first place to the physical sign mentioned by most surgical authors, and especially by M. Bauchet, viz., associated elevation of the tumour and the larynx and trachea during movements of deglutition. In this case, it was made out that neither the larynx nor the tumour moved during deglutition. This immobility of the larynx in cases of acute thyroiditis had, however, been previously observed by M. Gosselin, who attributed the absence of a sign generally considered as pathognomonic of affections of the thyroid gland, to prevention of movements of deglutition and of elevation of the larynx through inflammatory swelling and induration, and through muscular spasm excited by pain from such attempts. It became necessary, therefore, to investigate other signs before making a precise diagnosis. Extensive phlegmon was indicated by the diffused swelling, the deep-seated, hard, and irregularly circumscribed oedema, the erysipelatous blush, and the extension of the swelling to neighbouring parts. In favour of the diagnosis of thyroiditis, there were three rational symptoms: the preceding attack of hæmoptysis, which from the absence of any pulmonary lesion had been evidently caused by congestion of the larynx and trachea; next, the impeded respiration;

and, thirdly, the extreme dysphagia. In seeking for other reasons in favour of one or the other hypothesis, Professor Verneuil did not overlook the facts that thyroiditis is an exceptionally rare affection in the male, and that it hardly ever occurs save in the subjects of hypertrophy or cystic disease of the thyroid body, or in the inhabitants of a region where goitre is common. The patient had resided in a department where hypertrophy of the thyroid gland is frequently met with, and he stated that his neck had always been large. The case was finally diagnosed as one of thyroiditis, and the correctness of this view was confirmed by the subsequent course of the affection. After the application of a few leeches the swelling speedily subsided, the pain ceased, and the movements of deglutition and respiration became free. On August 12 the patient was discharged from the hospital as cured, but then presented a well-marked goitre. The following conclusions were drawn from the facts connected with this case. 1st. Thyroiditis may assume the external characters of a large subaponeurotic phlegmon of the neck. 2nd. The diagnostic signs based on the circumscribed condition of the tumour, on its form and seat, and on its elevation during movements of deglutition, are not always present, or at least cannot in all cases be made out. 3rd. The diagnosis should be based mainly on the difficulty in deglutition, on respiratory disturbances and on altered phonation; it is necessary also to inquire as to the recent occurrence of an attack of hæmoptysis. 4th. The pre-existence of thyroidean hypertrophy, and the previous residence of the patient in a goitre-district, constitute strong presumptions in favour of thyroiditis. 5th. Local bleedings, practised early and freely, are probably of some efficacy in cases of this kind.

SCHÜLLER ON INJURIES TO THE SHOULDER.—Dr. M. Schüller, of Greifswald, in a contribution to the *Berliner Klinische Wochenschrift*, no. 37, 1876, on a simple guide to the differential diagnosis between fracture of the neck of the humerus and subcoracoid dislocation, alludes in the first place to the difficulty occasionally experienced by surgeons in distinguishing the one injury from the other, especially in fracture near the upper end of the humerus, in which the lower fragment, the shaft of the bone, is displaced inwards and into the axilla, whilst the upper fragment, the head of the bone, remains in the glenoid cavity. In this form of injury, which usually consists in fracture of the surgical neck of the humerus, the long axis of the arm runs obliquely inwards towards the coracoid process, the elbow stands away from the side of the trunk, and the deltoid muscle is flattened or even concave on its outer surface—all signs of forward dislocation of the head of the bone. In many instances a fracture may be readily diagnosed, partly through crepitation, partly from a determination of the characteristic form of the end of the lower fragment, and of the presence of the upper fragment just below the acromion. Occasionally, however, a precise diagnosis of this injury may be rendered impossible through much effusion of blood, absence of crepitation, and the small dimensions of the upper fragment. Attempts at reduction performed again and again are in such a case always followed by an immediate return of the abnormal condition of the shoulder. Sometimes it happens that in one of these attempts at reduction the surgeon is able to make out crepitus, and then assumes that he has himself produced the

fracture through the application of too much force. The author holds that under ordinary conditions it is impossible to produce fracture of the neck of the humerus in an attempt to reduce a dislocation at the shoulder. It often happens, however, that in a case of old fracture of the neck of the humerus, mistaken for and treated as a case of subcoracoid dislocation, the fragments are again separated in an attempt at reduction. The author does not altogether disapprove of the administration of chloroform in cases of doubt, but holds that apart from the fact that there may be cases in which the doubt cannot thus be cleared up, it would be more desirable to have some means of making the diagnosis surely and safely without anæsthesia. The method suggested as very simple and ready in its application is that of measuring the injured extremity, and especially the distance between the acromion and the point of the epicondyle. In every case of fracture of the neck of the humerus this distance is shorter on the injured than on the sound side, and this shortening is greatest in those cases which most resemble subcoracoid dislocation of the head of the bone. In this latter injury the distance between the above-mentioned anatomical points is increased. The author does not agree with Malgaigne, who held that this increase in the length of the arm is not constantly met with in cases of dislocation. There is no difference of opinion, however, as to shortening of the arm in every case of fracture of the neck of the humerus with displacement of the shaft inwards. Shortening, which in this injury is usually considerable, is, as was acknowledged by Malgaigne, never met with in cases of dislocation. The author, when measuring the distance between the acromion and the external epicondyle, takes care that the arm is abducted, and the forearm flexed at a right angle. The round extremity, when measured, is placed in a similar position. The tape is then carried to the external condyle from the same point of the acromion on each side, and from either its anterior or its posterior angle.

W. JOHNSON SMITH.

BROWN ON THE PATHOLOGY OF BURNS AND THEIR RATIONAL TREATMENT.—Dr. Bedford Brown, of Alexandria, Virginia, writes as follows in the *Philadelphia Medical Times*. The first impression made upon the general system by the local action of intense heat is that of nervous shock. This condition is clearly understood. But there are certain coincidental morbid phenomena associated with shock, which are of more importance and less comprehended.

In those cases of excessive nervous shock caused by extensive burns, thrombosis of the heart and large veins entering the right side of that organ not unfrequently occurs. There are peculiar reasons why thrombosis should be a more common result of shock from burns than from almost any class of injury, this phenomenon being due to a combination of causes, one in the form of excessive nervous depression, the other from disorganised blood from the local action of heat which has been conveyed from the burned tissues to the centre of circulation. A few disorganised blood-corpuscles or a small portion of coagulated fibrin, or albumen, when carried into the general circulation, at once become nuclei for the formation of thrombosis of the heart and great vessels.

Hence the necessity of accurate diagnosis between simple nervous shock and thrombosis. In simple

shock the pulse, though exceedingly feeble, is not usually much accelerated, and is generally regular in rhythm. The cardiac sounds are very feeble, but distinct. The temperature is greatly reduced; the complexion is pallid; the respiration is but little increased in frequency, and there is an absence of præcordial distress, though nausea may be present.

On the contrary, in shock with thrombosis, the breathing is painfully laboured, and frequent. The action of the heart is tumultuous, irregular, feeble, and very frequent. The complexion is livid, while the skin is cold and bathed in perspiration; præcordial distress is painful, and the cardiac sounds almost obliterated.

There cannot be a rational doubt that death following extensive burns directly is often the immediate result of cardiac thrombosis.

Secondary Stages of Burns.—Following the reaction after the first shock to the nervous system has passed off, probably capillary embolism and its legitimate consequences constitute one of the chief causes of mortality. Here, as in thrombosis, those properties or rather constituents of the blood whose vitality has been destroyed in the burned tissues, not only become a septic source, but, after passing through the large veins and heart, find lodgment either in the pulmonic or the portal circulation, producing blood-stasis, hyperæmia, inflammation, and suppuration. Hence we generally see these peculiar phenomena in one or the other of these two circulatory systems. It is sometimes witnessed in the cerebral circulation, when symptoms of congestion, with active delirium, and finally coma, are prominent.

Thus we may have in the pulmonic system, as a result of capillary embolism, chill, followed by either pleuritis, pneumonitis, or abscess, with inflammatory fever; in the portal system, peritonitis, ulceration of the intestines, with either diarrhoea or dysentery, and abscess of the liver. In many of these cases all the characteristics of true pyæmia are developed. These microscopic embola appear not unfrequently to manifest a tendency to find lodgment in the mucous surface of the small intestine—for instance, the duodenum—and then induce ulceration. This is probably due to an effort of nature to eliminate them from the circulation. As evidence of the fact that mere extent of burned surface is not always the cause of death, numerous instances of very extensive burns have come under the observation of the writer, which were progressing favourably in the healing process, when suddenly symptoms of capillary embolism, congestion, and inflammation of some internal organ, or ulceration with dysentery, appeared and speedily terminated the case.

On the Local Changes in the Tissues from Burns.—No other variety of injury either from mechanical or chemical cause is attended with such protracted and unceasing pain as that from burns. We often see far greater destruction of tissue from other causes followed by but little pain, and which are much more rapidly healed. This peculiarity of burns is doubtless due both to the exposure and injury of the terminal branches of sensitive nerves. The constant tendency to contract in burned tissue, whether vascular or fibrous, produces unceasing pressure around these inflamed nervous termini, and causes incessant pain, until finally, by this compressing process, their organisation is destroyed, as is indicated by the great want of sensibility in the cicatrix.

While it is true that the destruction of vascular

and fibrous structures by the action of intense heat is a leading difficulty in the way of healing these wounds, the irritation constantly present caused by the myriads of inflamed and sensitive nervous branches is equally a cause of protracting their progress. Then, in the healing process of burns, painfulness and contractility are among the distinguishing features.

This is true even of the granulations which form the new tissue. They are firm, more cartilaginous, more sensitive and painful, and their structure more contractile than any other. Here again, may not this in part be due to those minute bulbs of the inflamed nervous branches keeping up an unceasing irritation?

This peculiar contractility of burned tissue not only tends to obliterate the nervous branches entering it by compression, but also tends to diminish the calibre of capillary vessels to such an extent as to comparatively unfit them as the carriers of blood-corpuscles. Hence this newly formed cicatricial structure is reduced somewhat to the standard of cartilage, and is no longer subject to those active vital operations of disintegration, waste, and renewal to which other more vital tissues are. Therefore, whatever form they assume is permanent. In this manner the nervous supply is curtailed, causing a diminished sensibility and circulation in the cicatrix.

General Treatment of Burns.—In the treatment of simple primary shock, while all concede the necessity for anodynes, the free use of diffusible stimuli and the sulphate of quinine are of great importance. The process of nervous shock in these cases has some analogy to chill, as when reaction returns it is disposed to assume the form of fever. The quinine in such cases not only aids in restoring reaction, but it also moderates it, and prevents a high degree of febrile excitement.

In shock with cardiac thrombosis, opiates are dangerous. Quinine in large doses is too depressing, but in small quantities is useful. Ammonia in the form of the liquor, with iodide of potassium, and alcoholic stimulants, constitute the most important remedies.

Those cases of hectic fever arising during the progress of very extensive burns with copious suppuration, are best treated with a combination of tincture of the chloride of iron, chlorate of potash, and quinine. For instance, in a case of burn where the entire cutis from the toes to the hip was destroyed, the entire surface of the limb became a mass of suppurating granulations, the amount of pus excreted daily being enormous. Hectic fever, with great exhaustion, followed. This method of treatment was adopted, and in a month the hectic symptoms had disappeared, the suppuration subsided, and the extensive injury rapidly healed. In those cases of internal inflammation, suppuration, or ulceration arising from capillary embolism either with or without symptoms of pyæmia, those remedies are equally valuable, but they should be associated with antiseptics of a decided character; carbolic acid in the form of sulpho-carbolate of sodium is probably one of the best adapted of all this class for internal use. The external use of the acid owes its chief value to its antiseptic action over the system when absorbed. The question of sepsis in burns is a much more important one than is generally supposed.

Local Treatment.—Of all local applications, in the experience of the writer, iodoform, prepared with

extract of conium, and spermaceti ointment, with a small portion of carbolic acid, appears to meet the several indications best.

This agent acts as a certain and most effective sedative on the painful and irritable exposed surface, and at the same time as an antiseptic. It reduces irritation, inflammation, and suppuration when in excess, in a remarkable manner. It converts a most painful and irritable wound into one comparatively painless with promptness.

This remedy is also an excellent promotive of healthy action and of the healing process. The use of this preparation has another advantage: it renders the constant use of anodynes unnecessary. The following formula has been found the best:

R. Iodoformi, ʒij
Unguent. cetacei, ʒj
Ext. conii, ʒjss;
Acid. carbol. gtt. x.—M.

This ointment is spread twice daily on soft linen, and applied over the inflamed surface, and then enveloped in oiled silk. No other dressing is necessary. The only objection to the use of this remedy is its peculiar odour. In those cases of burns attended with great dryness of surface from destruction of vitality and want of exhalation, the wound, before being covered with the iodoform ointment, should be coated over with the common linimentum calcis. This affords a soft and moist dressing, which in no wise interferes with the action of the iodoform.

MATERIA MEDICA AND THERAPEUTICS.

PAVESI ON THE ANTIZYMOTIC TREATMENT OF DIPHTHERIA.—Dr. Pavesi describes, in the *Annali di Chimica Applic. alla Medicina*, 1876 (abstract in *Annali Universali di Medicina*, August), a formula which he recommends in the treatment of diphtheria. It is founded on the antizymotic properties of chloral, salicylic acid, and the sulphites. It is as follows: \mathcal{R} Chloral hydrate, salicylic acid, glycerine, sulphite of soda, each $1\frac{1}{2}$ parts; distilled water, $3\frac{1}{2}$ parts; spirits of wine, 1 part. The whole is put into a strong glass vessel, which is closed, and exposed to a heat of 100° to 120° Fahr. for a few minutes, until the sulphite, salicylic acid, and chloral are completely devolved. A homogeneous solution is produced, which is filtered through bibulous paper, and preserved in a well-closed vessel. It is an oily, limpid, colourless liquid, having the odour of its constituent parts. It is insoluble with water. On the application of proper tests, the chloral, salicylic acid, sulphite of soda, and glycerine are found to be unchanged.

Used both internally and externally, it is an energetic antiseptic, antifermentative, disinfectant, hæmostatic, and preservative, as well as a destroyer of parasitic organisms. Dr. Pavesi says that it may be used as an antiseptic, and also as a sedative, in a large number of diseases.

FERA ON THE USE OF SULPHATE OF IRON IN DIPHTHERIA.—In an article in the *Gazzetta Medica delle Calabrie* for January (abstract in *Annali Universali di Medicina*, August), Dr. Fera asserts that he has treated eighty cases of diphtheria successfully, without one death, by the local application of powdered sulphate of iron. He describes the mode of treatment in the following terms.

A brush is made of horsehair, which is cut at a distance of 3 or 4 millimètres (about $\cdot 12$ or $\cdot 16$ inch) from the handle. The brush is then dipped in very finely powdered sulphate of iron, and can be easily applied to the diphtheritic patches on the tonsils, pharynx, and velum pendulum palati, or elsewhere. Sometimes the brush is applied energetically to the diphtheritic area, until it bleeds freely; the pearly colour of the diphtheritic exudation at once disappears, and the surface becomes red, or some portions of the area may be covered with mucus, which is detached by the next application. The application is made twice daily. After the first or second, the febrile temperature is gradually lowered; the enlargement of the cervical glands is reduced and entirely disappears; and in three or four days the patients are well.

TIZZONI ON THE LOCAL ACTION OF CHLORAL HYDRATE.—In an article in *L'Indipendente*, no. 6, 1876, Dr. Guido Tizzoni of Pisa observes that the first effect of the application of solution of chloral hydrate to parts deprived of epidermis and epithelium is a transient irritation, varying in degree with the strength of the solution. This is followed by an anæsthetic action, in regard to which the observations of Drs. Coignard, Horand, and Puech, have been confirmed by the author.

The irritant action favours the development of cellulo-vascular granulations, and accelerates the cicatrization of solutions of continuity. The chloral

acts also as an astringent, and as an antiphlogistic. The irritant action, which is generally of brief duration, having ceased, there is in a few hours an arrest of the inflammatory processes, including suppuration: this appears due to the retardation of the circulation and the constriction of the capillaries, as well as to minute coagula and embola, which are found in the vessels and cut off or diminish the local supply of blood—a fact which has been established by the experiments of the author and of Dr. Fogliata.

The most important properties of chloral in surgery are those which it possesses as a disinfectant, antiseptic, antiputrescent, and antifermentative remedy. The author has used it for the preservation of flesh, milk, urine, etc.; no change being perceived at the end of two months. He recommends chloral in ordinary surgical practice, as a preservative against local and general infection, and as a restrainer of suppuration.

He describes the experiments and clinical observations which he has made with regard to the action of chloral, especially as an antiputrescent. The ultimate results were always the same, differences depending only on the amount of chloral used. The solution which he employs is one of ten parts of chloral in fifteen of water.

He has treated, both in hospital and in private practice, many cases of acute and chronic urethritis with injection of chloral hydrate, in the manner recommended by Parona, and has found the result to be rapid cessation of the discharge, and cure of the disease without complications.

CAVAZZANI ON CAMPHORATED ETHER IN ERYSIPELAS.—Dr. Cavazzani gives the following formula in the *Gazzetta Medica Italiana Provincia Venete*: \mathcal{R} : camphor, 15 grains; tannin, 15 grains; ether, 2 drachms. This is painted every three hours, and sometimes oftener, over the affected parts. The author says that he has never seen this method fail, even in the most severe cases, in which ataxic and adynamic symptoms had already appeared. The fever soon diminishes, and the local erysipelatous process is arrested in two or three days.

In some cases of phlegmonous erysipelas, which Dr. Cavazzani had under his care, this treatment arrested the progress of the disease. Trousseau prescribed this drug only in cases of circumumbilical erysipelas in new-born children, and Guibout did not use this solution in phlegmonous erysipelas or in that affecting the face, fearing in the latter case that the meninges would become affected. In seeking an explanation of the action of the remedy, Dr. Cavazzani supposes that erysipelas is nothing else than a lymphatitis, and that the tannin exercises an astringent action on the cutaneous capillaries.

A. HENRY, M.D.

JERUSALIMSKY ON THE PHYSIOLOGICAL ACTION OF QUININE.—According to N. Jerusalemky (Berlin: Hirschwald, 1875, and abstract in *Centralblatt für die Medicinischen Wissenschaften*, no. 26, 1876), quinine given in small and medium doses (1 to 5 grains) always causes in dogs (rabbits and frogs are less suited for these experiments), an increase in the frequency of the pulse; it may be even doubled and more. Variations occur—but it never falls under the normal. The pulse sinks rapidly just before death. The blood-pressure, on the contrary, has in general the tendency to fall; only after each injection there is a short period, where, with varia-

tions, it rises somewhat; then it gradually falls under the normal, though not far under, as long as no large doses are given. Large doses (20 to 25 grains) cause the pressure to sink rapidly and generally at once, but the frequency of the pulse generally after a short acceleration. The acceleration of the pulse, as is shown by special experiments (section of the vagi, of the spinal cord at different heights), is the result of a depression or paralysis of the regulating and excitation of the excito-motor nervous system.

The condition of the blood-pressure—with medium doses a short increase lasting between twenty and sixty minutes, then sinking, notwithstanding increased pulse-frequency—is explained by the author through a complicated nerve-action. The increase is caused by paralysis of the regulating and stimulation of the vaso-motor apparatus. That the vaso-motor centre in the medulla participates is supported by this, that after its destruction the increase is only feebly expressed. The effect of quinine on the vessels was ascertained by direct observations on the frog, and specially by the experiments on the spleen to be presently cited. After the excitation of the vaso-motor centre paralysis follows very rapidly, which affects the peripheral vessels, the excito-motor cardiac ganglia, and the cardiac muscles. After large doses, the heart itself does not reply to direct stimulation. The conditions here mentioned are those which follow medium doses; after small doses the tonic action, after large the paralytic, is more pronounced. In man, the author after a moderate dose (10 grains) observed acceleration of the pulse, and increased heart-beat, which in one case increased to palpitation. The cause of the difference in the results between this and other authors, the author seeks to ascribe to difference in the animal employed.

The respiration is always increased by small doses, rendered slow by large doses, and also irregular with rapidly following asphyxia. This action arises from the effect on the respiratory centre. The hyperæmia and even the hæmoptysis observed by some authors after large doses of quinine are probably due to paralysis of the vaso-motor centre by the quinine.

The action on the temperature was not constant throughout. In most experiments it sank (at most 1.5° Cent. 2.7° Fahr.); in other cases it rose, and this after large doses, and in other cases it varied little from the normal. The author explains these results by the action of quinine on supposed nerve-centres. After section of the spinal cord, 1. between the sixth cervical and first dorsal vertebra there was pronounced increase of temperature (3° to 4° Cent. 5.4° to 7.2° Fahr.); 2. in the region of the second dorsal vertebra the reverse; and 3. under the second to the sixth dorsal vertebra, only slight modifications from the normal. The author assumes the existence of a heat-exciting centre, opposite the second dorsal vertebra, and a heat-regulating centre, between the sixth cervical and first dorsal vertebra, which influence the exchange of material through trophic nerves. The author explains the modification in temperature, by the relation of quinine to these two centres. The increase after large doses would therefore be produced by paralysis of the regulating centre.

The rapidity of the blood-current (investigated by Ludwig and Dogiels' Stromuhr) is much slowed by quinine, in the proportion of 1 : 2 and more. This phenomenon is specially to be ascribed to the

paralysis of the vaso-motor centre, for after its destruction quinine can only produce a very slight retardation.

With regard to the effect of quinine on the colourless blood-corpuscles, the author confirms the statements of Binz and his scholars. He also observed cessation of the amoeboid movements; emigration and diminution in the number of these bodies. Further, he observed that the corpuscles which had emigrated had for the most part a single nucleus, whilst previously the greater number were multinucleated. Like Manasséin, he observed that the red corpuscles became larger under the influence of quinine.

Confirming Mosler, he observed also the diminution in the size of the spleen; the organ becoming at the same time tougher, granulated on the surface, and of a brighter colour. After section of the splenic nerves (splenic plexus, or semilunar ganglion or splanchnic) or of the spinal cord, which produced of course a considerable swelling of the spleen due to paralysis of the vaso-motor nerves, the effect of quinine still occurred, though to a much less extent. It therefore depends primarily on the effect of the alkaloid on the peripheral nervous and muscular elements of the spleen, and secondarily on the splanchnic and central nervous system.

WM. STIRLING, D.Sc., M.D.

SOULEZ ON CARBOLISED CAMPHOR AND ITS THERAPEUTIC APPLICATIONS.—Dr. Soulez, of Romorantin, has a paper on this subject in the *Bulletin Générale de Thérapeutique*, Aug. 30. Desiring to combine the valuable properties of carbolic acid and camphor, and founding his proceedings on the property possessed by certain acids of liquefying camphor, Dr. Soulez poured 2 grammes (30 grains) of carbolic acid solution (in the proportion of nine of carbolic acid to one of alcohol) on 12 grammes (180 grains) of camphor in powder, in successive portions, taking care to keep the mixture agitated. This produced a liquid of a syrupy consistence. Carbolic acid dissolves a larger quantity of camphor than that just mentioned, but in practice Dr. Soulez contented himself with a solution of 2.50 grammes ($37\frac{1}{2}$ grains) of powder for 1 gramme (15 grains) of acid. The product thus obtained is an oleaginous liquid with the combined odour of camphor and carbolic acid, which boils at a slightly elevated temperature without decomposing, does not mix with either water or glycerine, is decomposed by concentrated alcohol with a deposit after some hours of crystals of camphor, is miscible in all proportions with olive and almond oils, if poured in a boiling state into cold water immediately solidifies into a mass, and produces a red colour on the addition of nitric acid.

For dressings, Dr. Soulez uses mixtures of a twentieth part of carbolised camphor, either with olive oil or with infusion of saponaria (100 grammes of saponaria leaves with 1,000 grammes of water) which makes an emulsion. A square of wadding soaked in the mixture of carbolised camphor and olive oil is placed in contact with the wound, and over this six other squares soaked in the emulsion of carbolised camphor and infusion of saponaria. To prevent evaporation, these are then covered with a thin layer of gutta-percha tissue, and the whole is secured by a piece of dry wadding as a bandage. It should be added that the whole wound, whatever be its nature, is washed before being dressed, with the emulsion. Thus applied,

says Dr. Soulez, this dressing realises all the favourable conditions inherent in Guérin's and Lister's method without its inconveniences. Usually the dressing is renewed every six days, sometimes being left in its place ten days, and up to the present time not the least irritation of the skin or of the wound has been observed, which could be attributed to contact with the carbolised camphor.

Dr. Soulez then proceeds to narrate some cases in which this preparation was successfully employed, and concludes by drawing attention to the following as the advantages derived from the employment of the carbolised camphor :—1. Diminution in reaction after great operations ; 2. Cessation or lessening of pain ; 3. Less abundance of suppuration.

W. DOUGLAS HEMMING.

SMITH ON THE PHYSIOLOGICAL ACTION OF SANGUINARIN.—Dr. R. M. Smith, of Philadelphia, has made, in the Physiological Laboratory of the University of Pennsylvania, a series of 153 experiments on cats, dogs, rabbits, frogs, guinea-pigs, pigeons, etc., with regard to the physiological action of sanguinarin, the alkaloid of *Sanguinaria Canadensis*, and arrives at the following conclusion (*Amer. Journal of the Med. Sciences*, Oct., 1876.) 1. Sanguinarin destroys life through paralysis of the respiratory centre. 2. It causes clonic convulsions of spinal origin. 3. It has no effect on either the motor or sensory nerves. 4. It causes marked adynamia and prostration from its depressing action on the spinal ganglia and muscles. 5. It decreases reflex excitability through irritation of Setchenow's centre, and by ultimate paralysis of the spinal ganglia, from large doses. 6. It produces in cats, dogs, and rabbits, a fall of pulse and blood-pressure, the fall of the latter being preceded by a temporary rise after the administration of proportionately small doses. 7. The fall of blood-tension is caused by a paralysis of the vasomotor centre, and by a paralysis of the heart itself, probably of its muscular structure. 8. The temporary rise in blood-pressure is due to irritation of the vasomotor centre, previous to its paralysis, by small doses. 9. The reduction in the pulse is due to direct action of the poison on the heart, through paralysis of its motor power. 10. Sanguinarin has no action on the liver. 11. It causes marked salivation. 12. It renders the respiratory movement slow by prolonging the pause after expiration. 13. This reduction is caused by loss of tonus of the respiratory centre. 14. Small doses cause an irritation of the respiratory centre, and consequently an increase in the number of respiratory movements. 15. Applied locally, sanguinarin soon causes complete paralysis of striped muscular fibre. 16. It always causes dilatation of the pupil. 17. It is an emetic. 18. It always lowers the temperature. 19. When introduced into the circulation, it diminishes muscular contractility.

THE INEFFICIENCY OF CARBOLIC ACID AS A DISINFECTANT DURING EPIDEMIC DISEASE.—The *New Orleans Medical and Surgical Journal*, November, 1875, reports the following as embodying the experience of the profession at New Orleans. 1. Carbolic acid, as used for the purposes of 'disinfection,' by the board of health in New Orleans during the years 1867-70-71-72-73-74 and 75, has failed to arrest small-pox, scarlet fever, and yellow fever. 2. Carbolic acid, as used for purposes of 'disinfection' by the board of health in New Orleans, has, in several instances, proved injurious to the in-

habitants of the 'disinfected' districts. 3. The facts observed in New Orleans during the practice of carbolic acid 'disinfection' upon a larger scale than ever before in the history of sanitary science, sustain the views held by the authorities that it is impossible to disinfect the atmosphere of an entire city, or even of a circumscribed area as of two or more squares. Cases of yellow fever have occurred in succession at long intervals in houses and localities which have been most thoroughly subjected to the so-called 'carbolic acid disinfection.' Instances have been observed where unacclimatised individuals returning from the country before cold weather had put an end to the disease, and entering those districts of the city in which carbolic acid had been most lavishly employed as a 'disinfectant' have been attacked with yellow fever. 4. Yellow fever has followed its usual course, increasing up to a certain period, and then declining with the fall of temperature, and ceasing with the appearance of the frost. No connection has been traced between the decline and cessation of the disease and the amount of carbolic acid used for purposes of disinfection.

DAREMBERG ON BEECH-TAR CREASOTE IN THE TREATMENT OF THE EXPECTORATION OF PHTHISIS. Dr. Georges Daremberg has first made a chemical analysis of the sputa of phthisical patients with great care ; he has shown that these sputa may contain almost as large a quantity of phosphates and chlorides as the urine, and that expectoration in these cases is one of the ways by which the products of denutrition are expelled ; this expectoration, however, is not only one of the ways, but also one of the causes of this denutrition, which is indicated by precise prognostic and therapeutic data. Beech-tar creasote has been employed in France by M. Bouchard, and in five cases of advanced phthisis the results have been favourable ; the expectoration has quickly stopped. From 20 to 40 centigrammes (about 3 to 6 grains) of creasote per diem were given. According to Hlasewetz and Barth this beech-tar creasote is a combination of creasote ($C_8H_{19}O_2$) with a carburetted hydrogen.

TALMY ON THE TREATMENT OF DIARRHŒA IN HOT COUNTRIES BY THE SUGAR OF MILK.—Dr. Talmy prescribes for the diarrhœa of hot countries from 20 to 300 grammes of sugar of milk daily. He administers it in the simplest way ; the sugar dissolved in a little water or as a syrup may be partly taken at each meal, or as a draught in the course of the day. An excellent mode of administration consists in putting the dose of sugar of milk to be taken into half a litre or two litres of milk, according to the habits and the digestive capacities of the patient. The treatment is spread over several months, diminishing the dose as nutrition becomes more considerable and easier. According to M. Talmy's little work (published by Coccoz, Paris) the endemic diarrhœa of hot climates is the result of a functional lesion of the liver, which results in the diminution and even the suppression of the glycogenic function of the liver. The sugar of milk may thus replace the glucose which is wanting in the blood.

CHALLE ON THE MARINE TREATMENT OF SCROFULA AND RICKETS.—Dr. Ernest Challe has specially noted, in the Hospital of Berck, the good effects obtained by treating scrofula by sea-water

and sea baths. The following figures, extracted from his 'Thèse de Paris,' show the results obtained in the year 1875.

	Boys.	Girls.	Total.
Cases in hospital on Jan. 1, 1875	258	253	511
Came into hospital in 1875	177	179	356
Total	435	432	867
Went out in 1875	193	213	406
Deaths	17	3	20
Total	210	216	426
Remaining on Dec. 31, 1875	225	216	441
Went out cured or much better	—	—	318

PSYCHOLOGY.

LAHR ON COLD WATER PACKING AND PROLONGED BATHS IN MANIACAL CONDITIONS.—In a paper read before the Psychiatrischer Verein at Berlin, and reported in the *Zeitschr. für Psychiatrie* (vol. xxxiii. part 3), Dr. Laehr says he considers this treatment particularly suited to the most troublesome class of cases which are met with in asylums, persons with whom almost literally one can do nothing; they refuse to be fed, to be washed, to be dressed, etc., they destroy everything, cover themselves and whatever is around them with filth, and are hopelessly stubborn and intractable. These are the patients who used to be subjected to prolonged mechanical restraint, but who are now for the most part treated to strong dresses fastened by leather straps and locks, and often dosed in vain with chloral and morphia. Dr. Laehr says that these patients are sometimes left naked in single rooms with merely some straw or rushes until their excitement has passed off, but we do not think that such treatment is practised in England at the present day. The author claims to have frequently seen the most surprising effects caused by prolonged baths and cold packs upon patients of this class, and he relates in full one such case.

Miss F., aged twenty-five, had been somewhat depressed, owing to family troubles, for about two years; she then became thoroughly melancholy, and was removed to an asylum whilst suffering from delusions of persecution, poisoning, etc., and refusing her food. She remained much in this state for eight months, but, just as she seemed to be improving, her mental condition became changed to one of violent excitement; she raved for hours together, ran excitedly about, had a ravenous appetite, was dirty in her habits, and practised self-abuse. The maniacal symptoms continued to increase, the patient shouted day and night, ran wildly about overthrowing the furniture, drummed with her feet against the wall, called herself by various titles, and refused all her food; she stripped herself, destroyed her clothing, and would not be dressed again; she pulled her hair out and was filthy in her habits. This state of things

had gone on for eight days, and the patient was greatly exhausted and reduced, with her temperature somewhat below normal, having slept only very few hours during the whole week, when the prolonged baths were commenced; they were given in the morning, and lasted from four to six hours; the patient appeared very comfortable, ate her food, and even fell asleep in the bath; in the afternoon the cold packs were applied, the patient soon fell asleep, and remained in them three or four hours. From this time improvement steadily progressed, but for a considerable period the same treatment had to be continued, for, when either the bath or the pack was omitted, bad symptoms always presented themselves again. Several months after the treatment ceased, the patient is reported as quite recovered.

HEMKES ON INSANITY FOLLOWING TYPHOID FEVER.—In a paper read before a psychological association in Hanover, and reported in the number of the *Zeitschrift für Psychiatrie* for September, Dr. Hemkes gives an account and an analysis of twenty-six cases of insanity following typhoid fever, which have been, during the last few years, under observation in the asylum at Hildesheim. Of these only seventeen are considered by the author to be undoubtedly due to the fever; in thirteen of them the mental symptoms were developed early during convalescence, and in the other four they appeared between three and twelve months afterwards, but the patients had never recovered from the weakness, emaciation etc., which the disease had caused.

The psychoses produced by enteric fever present no special characteristics which distinguish them from mental affections brought about by other causes, but Dr. Hemkes has been unable to find any recorded instance of general paralysis following this disease. Of the above seventeen cases, eight are reported as melancholia, eight as mania, and one as primary dementia. Among the seventeen there were six recoveries, three remain under treatment, the prognosis being uncertain, and one was discharged much improved and may have since recovered.

Short notes are given of the nine other cases, in which insanity followed *typhus abdominalis* after a period of from two to twelve or more years; as many writers hold that if there has been an attack of this disease in years gone by, it should generally still be regarded as a cause of insanity. Schlager and Jacobi, holding this view, have described the most frequent form of mental disorder under these circumstances as delusional insanity with delusions of persecution and hallucinations, and it is noteworthy that three of Hemkes' nine cases, in which the mental symptoms were not developed until after a considerable interval, took on this character. Among these nine cases there were only two recoveries.

As to the frequency of insanity caused by typhoid, Hemkes finds at Hildesheim only seventeen cases out of 1,500 to have been so caused; i.e., rather over 1 per cent., or, counting the other nine cases, about $1\frac{1}{4}$ per cent. Nasse has stated the proportion at 2 per cent. among a total of 2,000 patients; other observers have found rather larger numbers, but Bergman at Hildesheim stated the percentage as 38.

Psychoses following enteric fever, as well as the delirium occurring during its course, are regarded by the author as certainly due to anatomical changes in the brain and its membranes. Different investigators are not at present unanimous as to what these

changes are ; one party maintains that the symptoms are due to persisting hyperæmia of the brain with its results, while Griesinger and others point to anæmia and exhaustion as the cause. Buhl has described an oedematous condition of the brain and membranes with hyperæmia, and he believes that atrophy of the brain is also present. Hoffmann also found oedema, and has described in addition a diffuse yellow and brown spotted colouration of the cerebral substance, caused by pigment granules in the ganglion-cells. In some cases these granules were seen even in the nuclei of the cells, and had apparently caused their disintegration. This leads Hoffmann to describe the process as parenchymatous degeneration. These and other observers have also found considerable quantities of fat and pigment granules collected in the walls of the smaller cerebral vessels. The latest researches on this subject seem to be those of Dr. Leo Popoff (*Virchow's Archiv*, Bd. lxi.). He examined twelve cases which died from the second to the fourth week of typhoid fever ; the only appearances presented to the naked eye were a slight fulness of the vessels and occasional oedema ; but microscopical examination of the cortical substance revealed an infiltration of the brain-substance with small cellular elements resembling lymph-corpuscles ; these not only surrounded the ganglion-cells, but had often penetrated into them, in some cases so far as to exercise evident pressure on the nucleus. Popoff considers, then, that a number of the so-called migratory corpuscles enter the ganglion-cells, causing, in many cases, division of their nuclei, division of their protoplasm, and often destruction of the cell itself. A number of similar corpuscles were also found in the perivascular lymphatic spaces, and in the spaces surrounding the nerve-fibres. Like other observers, he noticed a deposit of fat and pigment granules in the walls of the vessels, and, beyond this, was often able to make out, in the smallest vessels, products of proliferation. The cells in the capillary walls were seen to be in a state of division, and were present in great numbers ; repeatedly in the lumen of the vessels the white blood-cells were extremely numerous, sometimes outnumbering the red cells, and in a few instances the vessel was filled with white cells only. All these appearances are considered to imply acute inflammatory mischief. This being so, says Hemkes, we can easily understand insanity following typhoid fever. He further says that probably cases in which only a small degree of anæmia or hyperæmia, with or without slight oedema of the brain and its membranes, exists, will recover under suitable treatment, but that where destruction of the ganglion-cells and considerable vascular changes have taken place, an incurable psychosis will probably be developed.

In a discussion which followed the reading of this paper, it was specially remarked that the delirium of typhoid fever, together with its surroundings, has not yet been sufficiently observed and described.

CHAS. S. W. COBOLD, M.D.

OBSTETRICS AND GYNÆCOLOGY.

ARLÈS ON INVERSION OF THE UTERUS TREATED BY THE ELASTIC LIGATURE.—At the meeting of the French Association for the Advancement of Science, August 23 (*Paris Médical*, September 7, 1876), Dr. Arlès read a paper on this subject. A woman

affected with inversion of the uterus had had seven pregnancies and three abortions. Dr. Arlès had in vain attempted reduction by the means usually employed. He resolved then to draw down the inverted uterus, and to surround it by a caoutchouc tube moderately closely. The results of the operation were very simple. The tumour was detached at the end of fifteen days. With this method of procedure, Dr. Arlès has never seen either hæmorrhage or peritonitis occur.

W. DOUGLAS HEMMING.

BOISSARIE ON INTRA-UTERINE FIBROIDS.—Dr. Boissarie gives (*Annales de Gynécologie*, Sept.) the history of a large intra-uterine fibroid in a woman aged forty-five years. At the vulvar orifice there was a large whitish mass, filling the pelvis ; it was impossible to reach the pedicle or the os uteri by the finger. As far as could be felt the tumour was free from adhesions. He tried to drag it outside the the vulva but failed, he therefore cut of all he could reach, with scissors ; having thus emptied the vagina he could feel the os and penetrate into the uterus, but not so far as the foot of the pedicle. The os had partly closed, and in a few days it entirely closed and the patient went away. In a few months she returned with the tumour again filling the vagina, and ulcerating where it came in contact with the air. He repeated the treatment with the result of the os completely closing, and now, after three years, the patient is perfectly cured. Dr. Boissarie is therefore contented with the result of partial removal of these large growths, as he believes that the time comes when their activity ceases, and they are absorbed ; and that this time coincides with the menopause.

COURTY ON REMOVAL OF INVERTED UTERUS BY THE ELASTIC LIGATURE.—Professor Courty relates (*Annales de Gynécologie*, September, 1876.) two cases of removal of the inverted uterus by the elastic ligature. In the first case, the uterus was removed by Dr. Courty after he had failed to reduce it. A caoutchouc tube was fastened round the neck of the uterus, and its ends fixed by a waxed thread very tightly drawn. This was tightened from time to time. At the end of thirteen days the tumour was completely detached. At the end of two months the patient was discharged, cured. The second case was done by Dr. Arlès, who applied the ligature in the same manner, and the uterus separated on the twelfth day, without any complication, leaving the operator astounded at the simplicity, harmlessness, and efficaciousness of the operation. In order to mark out more clearly the line of section, Dr. Courty proposes to burn a furrow round the uterine neck with the galvanocautery, in which the ligature will be more readily embedded.

FANCOURT BARNES, M.B.

GOELET ON A CASE OF ABSENCE OR NON-DEVELOPMENT OF BOTH UTERUS AND OVARIES.—The following rare case is related by Dr. A. H. Goelet in the *New York Medical Journal* for October.

Miss B., aged nineteen, consulted Dr. Goelet on February 12, 1876. She had never menstruated, and complained of constant severe headache, and of bleeding from the nose. The headache she had had as long as she could remember ; the epistaxis occasionally for the last five or six years, but not with any regularity. Otherwise her health was very good. Within the past three or four years she had consulted several physicians, who made unsuccessful

efforts to bring on her 'periods.' Her mother had also tried the usual domestic remedies, but likewise without success.

Her history led Dr. Goelet to suspect some congenital malformation, and he therefore advised an examination, to which she reluctantly consented. The points revealed were these.

1. The pudendum was entirely devoid of hair.
2. The vagina was a mere *cul-de-sac*, not more than two inches in length, and there was no evidence of a uterus at its extremity.
3. There was no uterus found after a thorough exploration of the pelvis. By conjoined manipulation—the index-finger of the one hand in the rectum and the other hand on the hypogastrium—the excavation of the pelvis could be explored with ease, the patient being very thin; and not even a rudimentary organ could be detected.
4. The mammae were wholly undeveloped.
5. She has never experienced any sexual sensations.

Dr. Goelet remarks that, judging from her history, and what was revealed by the examination, there was not only absence of the uterus, but also absence of the ovaries, or they were undeveloped.

He ordered bromide of potassium and hydrate of chloral for the headache, and this, he afterwards ascertained, afforded some little relief.

Such cases are extremely rare. A somewhat similar case was reported to the Royal Academy of Medicine in 1826, by Dr. Renaudin, at the age of fifty-two. She had never menstruated nor experienced any venereal passions, and the breasts were undeveloped. At the necropsy only a cervix uteri of the size of a writing-quill was found, but there was no uterus proper, and the ovaries showed very little development.

KIMBALL ON EXTIRPATION OF THE UTERUS IN CONNECTION WITH OVARIOTOMY: RECOVERY.—Dr. Gilman Kimball records (*Boston Medical and Surgical Journal*, August 31) the case of a patient, forty-eight years old, who had been operated on eleven years before for a cystiform ovarian tumour, which after removal weighed thirty-three pounds. She made a good recovery, and continued in good health for six years, about which time she noticed her abdomen was enlarging. In June, 1875, she was tapped, and forty-five pounds of brown coffee-coloured fluid drawn off, followed by extreme prostration. She was again tapped in October, and as these tapings only afforded temporary relief, and her health failing, she applied on November 5 to Dr. Kimball to again operate. An opening through the parietes, in the line of the former incision, was followed by an escape of several ounces of ascitic fluid. A cyst was tapped by a large trocar, and twenty-seven pounds of chocolate-coloured fluid were drawn away through a cannula, to which an India-rubber tube had been attached. The opening was enlarged and the cyst emptied. A semi-solid mass, composed chiefly of a large number of smaller cysts, was slowly drawn through the incision, care being taken all the while to keep the opening closed, as far as possible, against the ingress of atmospheric air.

The disease had embraced not only the uterus, but the whole of the left broad ligament. A separation of the parts thus involved was found impossible. Consequently, the extirpation of the entire uterus became an unavoidable necessity. A cluster of distended veins connected with the broad ligament was secured and severed between two ligatures.

The remaining tissues to be divided being thus considerably diminished in bulk, and especially in width, were next embraced in a loop of stout annealed iron wire, drawn tight by means of an *écraseur*. The operation was completed by severing the connection between the uterus and vagina by two or three strokes of the knife. The point of division was about three-fourths of an inch outside the iron ligature.

Before closing the wound it was found necessary to remove a considerable quantity of coagulated blood from the pelvic cavity. With some difficulty and delay a bleeding vessel was finally discovered, and secured with a carbolised ligature.

The pedicle, being short, was drawn forward and secured between the lips of the incision. The surface of the stump was thoroughly seared by actual cautery, and the wound closed with four deep sutures, three above and one below the pedicle.

During the entire period of convalescence there were no unpleasant symptoms. From first to last there were no signs of peritonitis or septicæmia.

MCBRIDE ON A CASE OF PUDENDAL HÆMATOCELE.—Dr. E. H. McBride reports the following case in the *Richmond and Louisville Medical Journal* for May. In April, 1875, he was called to see Mrs. L., mother of four children, and aged about thirty-five years. She had an enterocele in the right labium. It was very easy to reduce, but not easy to keep in place afterwards. The woman was in the third month of pregnancy. Dr. McBride used Gariel's air-pressary, but it could not be worn without great discomfort; he therefore abandoned all treatment except a band carried loosely around the body, to which was attached another band in front that passed over a compress on the tumour, and on through the perineal region to be fastened again on the back. It grew no worse; and when labour came on, it was only necessary to reduce it, which was done, and all went well. She was delivered of a fine daughter, and six months afterwards she felt quite well, the tumour having nearly disappeared.

Six months after her confinement, Dr. McBride was again called to see her hurriedly. She had been standing, the child in her arms, before the fire, and sat down with some force on a low chair in which was a large gourd with a neck three inches long. The sharp-pointed neck, being upwards, forced its way, in spite of her thick clothing, into the right labium at the posterior commissure, but the dress was not torn. The abrasion was very small. The neck of the gourd seemed to have passed along the mucous face of the right labium, leaving a black line, which was very hard. Five hours after the accident Dr. McBride found her with rigors, vaginal tenesmus, pulse denoting some prostration, caused by the excruciating, bearing-down pains she had felt for five hours, and some nausea and vomiting. On examination, he found a tumour larger than a goose's egg in the precise situation of the former enterocele; but unlike the soft reducible enterocele there was a hard, black clot, which seemed not to communicate with the abdomen, as there was no appreciable impulse produced by coughing. The tumour was so tender and sensitive that a thorough examination was impossible. There was no pulsation in the tumour. His diagnosis was pudendal hæmatocele; and with the aid of Dr. John McRae, an operation for the removal of the clot was done forty-eight hours after the accident, without chloroform. The

incision was made as directed by Dr. T. Gaillard Thomas. A large amount of coagulum and some pus were turned out of the sac. Nothing could be found of the enterocele. She rapidly recovered with but little sloughing. The after-treatment consisted in the use of injections daily of a weak solution of carbolic acid into the sac.

In his work on 'Diseases of Women,' Dr. T. Gaillard Thomas says: 'The accident in the puerperal woman is not very rare, but my experience would lead me to regard it as extremely so in the non-puerperal, since in a practice of nineteen years I have met with but one case. I have examined carefully the current medical literature of the day, and although it teems with reports of this affection as a complication on sequel of labour, I find no reports of instances in the non-pregnant woman.'

AYER ON A CASE OF IDIOPATHIC PERITONITIS COMPLICATING LABOUR.—Dr. James B. Ayer reports a case of this rare condition in the *Boston Medical and Surgical Journal* for May 25, 1876. On January 25, 1876, he was called to attend Mrs. C. D. B., aged thirty-seven, in labour with her first child. A year previously she had had a miscarriage. For two years she had been weak, and during the five or six months preceding confinement she found that the slightest exertion fatigued her, and she was compelled to give up her daily walk for exercise. For the last two months she complained of being very feverish. At times her breathing was very rapid. She had been jaundiced at frequent intervals since 1860, and had been told by physicians that her liver was much enlarged.

The labour was easy; the child weighing nine and half pounds, was delivered in ten hours after the first pains. The placenta followed quickly, and the uterus contracted readily and firmly. The perinæum was ruptured slightly. During the labour the patient frequently breathed rapidly and with difficulty. She complained of feeling very warm, and demanded that the doors should be open and the room kept cool. The temperature, a few minutes after delivery, was 100°; pulse, 88. There were no after-pains, and she slept quietly. Five hours after delivery Dr. Ayer found her jaundiced and the abdomen tympanitic. When pressure was made at either side of the uterus she experienced a slight amount of pain. She had had no chills nor vomiting. Pulse 90; temperature 100½°; respiration 35. There were five yellow stools during the day.

On the 27th she had slept well, and was now comfortable. Pulse 90; temperature 101°; respiration 30. The heart and lungs were found healthy. The abdomen was as tense as a drum. An enema containing turpentine brought away a large amount of wind. There was slight pain at the sides of the uterus on hard pressure. The diarrhoea had ceased.

On January 28, the patient was cheerful, and said that she had a good appetite. The breasts were filling with milk, and the child when put to them, nursed well and seemed satisfied. There was no pain over any part of the abdomen, even when considerable pressure was made.

On January 29, the temperature rose suddenly last night to 104°, and remained nearly as high. The patient, however, was comfortable; the skin was not very hot; tongue moist. The lochia were scanty. The perineal wound appeared to be healthy. During the next two days the temperature remained high; the patient, however, had no pain. Towards mid-

night on the 31st, she became unconscious, and died a few minutes later, on the sixth day after delivery.

The necropsy showed that the whole peritoneum was inflamed, and, in numerous places, lined with a purulent secretion. The abdominal cavity contained a pint of sero-purulent fluid. The uterus was well contracted, and both its inner lining and its substance were found in the condition which would be expected on the sixth day after delivery. The Fallopian tubes, ovaries, and broad ligaments showed nothing characteristic of disease. The liver was much enlarged, weighing about five pounds; it was otherwise normal. The heart was healthy. The lower lobe of the left lung was cedematous; the lungs were otherwise healthy. Each pleural sac contained six or seven ounces of serum. The other organs were healthy.

The healthy appearance of the uterus and of its attachments proves that this case could not have been one of ordinary puerperal peritonitis. On the other hand, the feverish symptoms and rapid respiration (in which the abdominal muscles took no part) noticed several weeks before confinement in connection with a temperature of 100° at the close of an easy labour, and with the absence of rigors, point to a peritonitis of latent character developed previously to confinement.

Dr. Ayer remarks that according to Hervieux and Fordyce Barker, cases of uncomplicated peritonitis, where no other pathological modification is found, are extremely rare. This case is peculiar on account of the absence of many of the diagnostic symptoms of peritonitis. We should have expected rigors and vomiting, arrest or suppression of the mammary secretion, together with a flabby condition of the mammae and a soft, uncontracted condition of the uterus. The pale face, sunken eyes, and collapsed cheeks of peritonitis were not present in this case.

In regard to the absence of pain, Schröder mentions cases where the inflammation had involved the whole peritoneum, as proved by necropsy, where only slight abdominal pain was noticed, and that limited to each side of the uterus. Churchill mentions five cases of intense general peritonitis where there was no pain nor tenderness whatever.

REPORTS OF PROCEEDINGS OF THE INTERNATIONAL MEDICAL CONGRESS IN PHILADELPHIA.

The following are summaries, taken from the *Medical News and Library*, of the principal papers read in the several sections of the International Medical Congress.

September 4.—SECTION I.—MEDICINE.

Typho-Malarial Fever: Is it a Special Type of Fever?—Surgeon J. J. Woodward, United States Army, made some preliminary remarks on the mortality of armies from disease, with comments on the comparison recently drawn by Professor Virchow between the mortality of the United States armies during the late civil war and that of the German armies during the war with France. He referred to the fatality of camp-fevers during the American civil war, and to the general belief among medical officers early in the war that these fevers represented a 'new type of disease.' The history of the introduction of the term typho-malarial fever was then given, and the proposition submitted that whenever great armies campaign in malarial regions the prevalent fevers are hybrids, between the malarial fevers and some form of typhus. Historical illustrations were drawn from (a) the siege of Naples, 1528; (b) the Hungarian campaigns, from 1526 to 1788; (c) the morbus mucosus of Roederer and Wagler; (d) the Walcheren expedition of 1809; (e) Virchow's comments on the fevers of the German army in France. Dr. Woodward then remarked on the distribution of malarial fevers and of typhoid fever in the United States, and on their relation to season of year; on the substitution of malarial fevers in particular regions, or at particular times, by typhoid; on the early recognition of hybrid forms by Drake; and on the recognition of similar hybrids by European authors as well as by Americans. The author then referred to the typho-malarial fever of the civil war. This term, he said, was never meant to represent a specific type of fever, but intended to designate all the many-faced brood of hybrid forms resulting from the combined influence of the causes of malarial fevers and of enteric fever. He then sketched the symptoms and pathological anatomy, and referred to the two great groups of cases—those in which the malarial element predominates, and those in which the typhoid element predominates; and to the scorbutic taint as a complication of either group during the civil war. After discussion, the section adopted as its opinion the following conclusion. Typho-malarial fever is not a special or distinct type of disease, but the term may be conveniently supplied to the compound forms of fever which result from the combined influence of the causes of the malarial fevers and of typhoid fever.

SECTION II.—BIOLOGY.

Microscopy of the Blood.—Dr. C. Johnston, Professor of Surgery in the University of Maryland, referred to the original source of blood in vertebrates; elements of blood in vertebrates; the normal elements having form exclusively considered, as regarded from two points of view—(a) that of anatomy

and physiology, and (b) that of medical jurisprudence; genesis of corpuscles; form of coloured corpuscles and their structure; leucocytes; size of coloured corpuscles; their enumeration; the coloured blood-corpuscles in medical jurisprudence. The paper was descriptive, and no conclusions were presented.

SECTION III.—SURGERY.

Antiseptic Surgery.—Dr. John T. Hodgen, Professor of Surgery in St. Louis Medical College, opened a discussion on antiseptic surgery, and laid down the following propositions. 1. Putrefaction may and does occur in the solids and liquids of the body, both with and without the direct contact of germs borne in the air or water. 2. Putrefaction of the solids and liquids of an open wound may in many cases be prevented if the contact of living germs with the surface is not permitted, or by destroying their vitality after contact with it. 3. It is possible that the living solids and liquids of the body may be so altered that they shall not furnish the conditions necessary to putrefaction. 4. Practically, the conditions to be met in preventing putrefaction are so difficult that in many cases it is impossible to comply with them. Yet, even partial success is eminently worthy of our best efforts. The debate was prolonged and was adjourned to the next day.

SECTION IV.—DERMATOLOGY AND SYPHILOLOGY

Variations in Type and in Prevalence of Diseases of the Skin in different Countries of Equal Civilization.—The subject was introduced by Dr. James C. White, Professor of Dermatology in Harvard University. The section adopted the following conclusions. 1. Certain obscure affections, the etiology of which is little if at all understood, even in those parts of Europe to which they are mostly confined, may be regarded as practically non-existent in America—of such are prurigo, pellagra, and lichen exudativus rubra. 2. Certain diseases, directly connected with and dependent upon poverty and habits of personal uncleanness, are less prevalent in the United States than in those parts of Europe of which we have sufficient statistical information for comparison. Examples of this class are the animal parasitic affections especially. 3. Some cutaneous affections of grave character, which are dependent upon, or a part of serious constitutional disorders, are of less frequent occurrence and of milder type amongst us than in Europe in general, or those parts of it where they are endemic. Lupus, the syphilodermata, and leprosy are the most marked instances of this class. 4. Certain disorders of the skin, especially those of its glandular systems, and those connected more immediately with its nervous system, are apparently more prevalent with us than in Europe. The most notable examples of the former are seborrhoea, acne, and possibly the heat-rashes; of the latter, herpes, urticaria, and pruritis. In addition to the above-mentioned conclusions, the following additional proposition was adopted by the section. 5. The type of certain acute congestion and nervous diseases of the skin is more severe in this country than abroad.

SECTION V.—OBSTETRICS.

The Causes and the Treatment of Non-Puerperal Hemorrhages of the Womb.—Dr. William H. Byford, Professor of Obstetrics in Chicago Medical College, approached a sequential classification by showing—

(a) That the uterus is prone to hæmorrhage, because of the conditions connected with menstruation; (b) That the causes of metrorrhagia act by aggravating these conditions; (c) That these causes sometimes have their origin in the nervous system, and sometimes in the vascular; (d) That of the latter causes some operate by increasing the flow of blood through the uterine vessels, while others effect the same results by retarding the current of blood in them. The mode of treatment advocated consists—(a) In removing the causes, and (b) in surgical, mechanical, and medicinal means to check the flow in great emergencies.

SECTION VI.—OPHTHALMOLOGY.

The Comparative Value of Caustics and of Astringents in the Treatment of Diseases of the Conjunctiva, and the best mode of applying them.—Dr. Henry W. Williams, Professor of Ophthalmology in Harvard University, spoke of affections of the conjunctiva in which neither caustics nor astringents are indicated; of the various forms of conjunctivitis, and the extent in which caustics or astringents may be usefully applied; of the modes of applying these remedies to best advantage; and of complications—in which the conjunctivitis is the result of other morbid processes—or in which the existing morbid conditions are the consequence of previous conjunctivitis, with the treatment of such complications. The conclusions offered were, after slight amendment, adopted by the Section.—1. In a considerable number of essentially transient affections of the conjunctiva, and in pterygium or other growths, no active treatment by caustics or astringents is required. 2. When disease affects only a limited portion of the conjunctiva, as in phlyctenular inflammation, the mildest stimulating or astringent remedies are usually sufficient. 3. In the acute and chronic forms of general conjunctivitis, astringents are, as a rule, safer, as well as more efficacious, than caustics, and therefore better adapted to the requirements of the general practitioner.

SECTION VII.—OTOLOGY.

The Importance of Treatment of Aural Diseases in their Early Stages, especially when arising from the Exanthemata.—Dr. Albert H. Buck, of New York, introduced the subject. His remarks were based exclusively on affections of the middle ear associated with the formation of pus, the serious nature of this form of disease oftentimes impairing the hearing very markedly, and occasionally terminating in death. He remarked that the anatomical relations of the middle ear afford an explanation of the serious results that may follow an acute inflammation of these parts; on the impotent nature of the means commonly employed for the relief of such an inflammation. He commented on the great value of paracentesis of the membrana tympani as a preventive of chronic purulent inflammation of the middle ear and all its serious consequences. The general practitioner was urged to acquaint himself with the use of the speculum and mirror. The Section adopted the following conclusions. 1. Chronic otorrhoea is at the present time a very common disease, due in most cases to the want of proper treatment during the acute stage of the affection. 2. It is by no means a harmless affection. 3. It may be fairly classed as a preventable disease; at least among those who possess a healthy constitution. 4. Paracentesis of the membrana tympani, if resorted to

during the first few days of the acute attack, and if not carried out too timidly, *i.e.*, if a free incision be made, and not a mere prick, is almost a sure preventive of the subsequent chronic disease. 5. The profession at large, and especially the medical schools, should give the subject more earnest thought than they have in the past.

SECTION VIII.—SANITARY SCIENCE.

Present Condition of the Evidence concerning Disease-Germs.—Dr. T. E. Satterthwaite, of New York, first considered the (1) vegetable germ-theory in contradistinction from other prominent theories, especially (2) the bioplasm theory, and (3) the physico-chemical theory. Especial attention was directed towards the following general topics:—(a) The agency of minute organised particles of a vegetable nature in the production of fermentation and putrefaction; (b) the epidemic diseases of certain plants and animals in their relation to minute vegetable organisms; (c) rapid multiplication of bacteria *pari passu* with the rapid spread of disease manifestations throughout the system; (d) the constant ratio between the most active changes in the so-called septic diseases, such as pyæmia, erysipelas, and puerperal fever, with the numerical increase in bacteria at the points involved; (e) can any strictly chemical substance be a fever producer? (f) bacteria and disease poisons: their capacity for successfully maintaining active properties; (g) inoculation of bacteria in healthy tissues. The following special topics were considered.—1. Bacteria: (a) their classification; (b) diagnosis; (c) appearances under varying conditions. 2. The poisonous fluids of infective diseases, as regards their physical properties and the solid particles contained in them. 3. The value of vacuum-tube experiments. 4. How far are either the bioplasm or the physico-chemical theories competent to explain the spread of infective diseases? 5. The poisons of special diseases, such as cholera, small-pox, the carbuncular diseases of men and animals, typhus and relapsing fevers, and diphtheria, in their relations to minute organisms. 6. The author's conclusions, after slight modification, were adopted as the opinion of the Section. 1. So far as inquiry has been made as to the results of the active principles in infective diseases, it is probable that in a certain number the matter is particulate or molecular in form, and, in the instances named, in no sense a soluble substance. 2. In regard to the causes of septicæmia, pyæmia, puerperal fever, erysipelas, and hospital gangrene, and in cholera, small-pox, the carbuncular diseases of men and animals, of typhoid and relapsing fevers, and diphtheria, there is not satisfactory proof that they are necessarily connected with minute vegetable organisms. 3. The real nature of these causes is still uncertain.

SECTION IX.—MENTAL DISEASES.

Microscopical Study of the Brain.—Dr. Walter Kempster, Physician and Superintendent of the Northern Hospital for Insane, Oshkosh, Wisconsin, gave a brief statement, outlining the progress made by recent investigators in studying the pathological histology of the brain in insanity, and the following subjects were introduced:—(a) The importance of microscopic observations of the several cerebral membranes, to determine their pathological condition, and the relations that the various pathological states hold to the forms of mental aberration; (b) The abnormalities in arterioles and capillaries, in-

cluding the various deposits on the walls of the vessels; engorgement and its consequences; the several changes observed in the coats of the vessels; occlusion from minute thrombi; and embolism; alterations in the course of the vessels, and the effect these conditions have upon the surrounding brain-tissue. (c) Miliary aneurisms and miliary hemorrhages; the effect they have in the production of brain disease. (d) The perivascular sheath, and perivascular canal, as they are found in cases of insanity, considered in their relations to adjacent brain-tissue. (e) The various alterations of structure and form noted in nerve-cells and nerve-fibres, in the several forms of insanity. (f) The abnormalities in the neuroglia, and the conditions called 'miliary sclerosis' and 'colloid degenerations' were described, and the influence each condition has in impairing normal cerebral action was discussed. (g) The various pathological conditions found in the microscopic examination of the brain in a number of cases of insanity were illustrated by means of photo-micrographs and lantern views.

September 5.—SECTION I.—MEDICINE.

Are Diphtheritic and Pseudo-membranous Croup Identical or Distinct Affections?—Dr. J. Lewis Smith, Physician to the New York Infants' Hospital, introduced the discussion on the question. The points made by the author were, that croup is a local malady, and that diphtheritic laryngitis is the expression or manifestation of a general malady. He referred to the anatomical characters of the affections, and adduced evidence to show that they are identical in kind as regards the state of the larynx, but differing in degree or intensity. He illustrated his remarks by clinical facts, which indicated their duality. The following conclusion was adopted by the Section. In view of the wide diversity of opinion at present existing as to the relations between diphtheria and croup, the Section on Medicine prefers to recommend the paper of Dr. J. Lewis Smith, to the Congress for publication, with the expression of their opinion of its high value as an important contribution to the literature of the subject, but without the expression of any definite conclusion upon the point at issue.

SECTION II.—BIOLOGY.

The Excretory Function of the Liver.—Dr. Austin Flint, Jr., Professor of Physiology in Bellevue Hospital Medical College, presented the following conclusions, which were adopted. 1. Cholesterin exists in health in the bile, blood, and nervous matter, also in the crystalline lens, the spleen, and meconium. 2. Cholesterin is formed for the most part in the nervous matter, from which it is passed into the blood. The blood gains cholesterin in its passage through the brain. Its formation is constant, and it is always found in the blood. 3. Cholesterin is separated from the blood by the liver, and discharged with the bile. It pre-exists in the blood, serves there no useful purpose, and, if allowed to accumulate, blood-poisoning results. 4. The bile has two separate and distinct functions, one connected with nutrition, to which the so-called biliary salts, glycocholate and taurocholate of soda, contribute; these do not exist preformed in the blood, but are products of secretion. The second function of the bile is excretory, connected with depuration or excretion; this is accomplished by the removal of the cholesterin which it obtains from the blood. 5. Normal fæces do not contain cholesterin. The latter substance is repre-

sented by stercorin, formerly called serolin, into which it is converted in its passage down the intestine. The conversion of cholesterin into stercorin does not, however, take place when digestion is arrested or when it is not necessary, as is shown by the presence of cholesterin in its own form in the fæces during fasting, and in the meconium. 6. The difference between the two varieties of jaundice, one mild and the other severe, is dependent on obstruction of the bile-ducts in one instance, with reabsorption of the biliary colouring matters, while in the other there is retention of cholesterin in the blood in consequence of destruction of the parenchyma of the liver. 7. That condition of the blood dependent upon the presence of cholesterin in the blood is called cholesteræmia. It is characterised by symptoms referable to the brain, and may or may not be attended with jaundice. 8. Cholesteræmia does not occur in every disorder of the liver, because, even when a part of the organ is disorganised, there may remain a part still capable of performing the functions of excreting cholesterin. 9. In cases of simple jaundice, even when fæces are decolourised, there is no accumulation of cholesterin in the blood. 10. Cholesterin bears the same relation to the liver as urea does to the kidneys.

SECTION III.—SURGERY.

Antiseptic Surgery.—The afternoon was devoted to the continuation of the discussion of the previous day on Antiseptic Surgery, the principal speaker being Mr. Joseph Lister, of Edinburgh. His remarks were illustrated by a partial demonstration of his antiseptic method. The section decided that it was unable, in the present state of the subject, to come to any distinct conclusion in regard to the antiseptic method.

SECTION IV.—DERMATOLOGY AND SYPHILOLOGY.

Are Eczema and Psoriasis Local Diseases, or are they Manifestations of Constitutional Disorders?—Dr. L. D. Bulkley offered the following conclusions, which were adopted. 1. Eczema and psoriasis are distinct diseases. The former is to be clearly distinguished from artificial dermatitis, and the latter from the eruptions of syphilis, scaly eczema, and leprosy. 2. Eczema and psoriasis cannot own a double causation or nature, at one time local and at another constitutional; but, with other diseases, may have a twofold cause, a predisposing and an exciting. 3. Eczema and psoriasis in many of their features resemble the accepted constitutional diseases more than they do those recognised as local. 4. Eczema is most properly likened to catarrh of the mucous membranes; it is very probable that some attacks called catarrh are eczema and psoriasis of the mucous tissue. 5. Both eczema and psoriasis resemble gout and rheumatism in certain respects, and are dependent upon a somewhat similar, although as yet unknown, constitutional cause; much of the skin-lesion must be looked upon as the local result or remains of the diseases. 6. There as yet exists no microscopical or physiological proof that eczema and psoriasis are the sole result of local cell-disorder, either congenital or acquired, or due alone to perverted nerve-action. 7. Local causes play a very important part in the etiology of eczema. They are probably inoperative in psoriasis. 8. Local treatment is often insufficient alone to remove the lesions of eczema and psoriasis, and cannot prevent or delay relapses; its success does not necessarily demonstrate the local nature of these affections. 9. Con-

stitutional treatment, alone and singly, can cure many cases of eczema and psoriasis, and prevent or delay relapses in a certain proportion of cases; under constitutional treatment is included every agency not properly classed among local measures. 10. The total weight of evidence and argument is that eczema and psoriasis are both manifestations of constitutional disorders and not local diseases of the skin.

SECTION V.—OBSTETRICS.

The Mechanism of Natural and Artificial Labour in Narrow Pelves.—The subject was introduced by Wm. Goodell, Clinical Professor of Diseases of Women in University of Pennsylvania. Regarding the mechanism alone of labour in narrow pelves, the following conclusions were reached. 1. The unaided first-coming head, and the aided after-coming head, observes in a flat pelvis precisely the same general laws of engagement and of descent. Hence, version here means art *plus* nature. 2. The forceps, however, applied in a flat pelvis antagonises more or less with the natural mechanism of labour. Hence the forceps here means art *versus* nature. 3. The aided and the unaided first-coming head observe in a uniformly narrow pelvis precisely the same laws of engagement and of descent. But version violates these laws. Hence, the forceps here means art *plus* nature; version, art *versus* nature. 4. That at, or above, the brim of a flat pelvis, the fronto-mastoid, or even the fronto-occipital, application of the forceps interferes less with the moulding of the head, and violates the natural mechanism of labour less than the biparietal pelvis. 5. In the flat pelvis, the vectis aids the natural mechanism of labour, and therefore meets the indications better than the forceps.

SECTION VII.—OTOLOGY.

What is the best Means of Testing the Hearing? Dr. Charles H. Burnett, Aural Surgeon to the Presbyterian Hospital in Philadelphia, considered (1) The character of the three principal tests (the watch, the tuning-fork, and speech) in use among aurists; the manner in which these tests are heard by the normal ear, and wherein the diseased ear fails to hear them. 2. Deficiencies and discrepancies in the hearing power of the diseased ear. In some cases the power to hear certain sounds in the musical scale drops out, while the power to hear others remains comparatively good. Can disease be diagnosed by the manner in which an ear hears certain tests? If so, what will give most aid in such a search? Most probably the voice. 3. Manner of Testing.—The following subjects were treated of:—(a) The importance of isolation of the better ear during the test in one-sided deafness. In any case, it is important to know how much is heard through the air, and how much is conveyed through the bones of the head. Want of precision in this has led to great errors in diagnosis and prognosis, in cases in which the nerve is good, but in which the sound-conducting apparatus, chiefly the middle ear, has been greatly diseased. (b) Consideration of what is needed for any form of test. An arbitrary sound unit may be established. An apparatus might be made to give out a set of notes of fixed value. It was considered how far the demands of any test are met by the watch, tuning-fork, and human voice. Conclusions favourable to the latter were drawn from the preceding remarks, with the recommendation of a series of test-words.

SECTION IX.—MENTAL DISEASES.

Responsibility of the Insane for Criminal Acts.—The following is a summary of remarks made by Dr. Isaac Ray, of Philadelphia, in opening the discussion. Great differences of opinion exist on the question how far insanity shall be admitted as an excuse for crime. Lord Hale's doctrine that partial insanity—that in which the patient is reasonable and correct on many subjects—does not necessarily exempt one from the penal consequences of crime, still shapes the decisions of English and American courts. Tests for determining what kind of partial insanity does and what does not excuse for crime are diverse, unsatisfactory, and none supported by correct scientific knowledge of insanity. Delusion has been decided to be a sufficient excuse only when the criminal act committed under its influence would have been legally justified had the delusion been true. Notwithstanding many of the insane think and act correctly to some extent, yet it is impossible to say with any near approach to certainty in any given case, where sanity ends and insanity begins. Two mistakes are made by lawyers in estimating the responsibility of the insane, viz., they define the scope of the influence of the mental disorder in an arbitrary manner, unsupported by the facts of psychological science, and they regard the affective faculties as without any part in the play of disease. The latter mistake pervades the theories of the law and the judgments of those who pretend to no law. The moral, like the intellectual, faculties are dependent for their exercise on the brain—the larger part of the brain probably being devoted to this purpose. Consequently, disease of the brain must necessarily affect the manifestations of these faculties. Whether the one or the other class, or both, is affected will depend on the part of the brain diseased. Sanity supposes the integrity of all the faculties, moral as well as intellectual. If this integrity be destroyed insanity is the result, wherever the lesion may be. Whatever faculties may be affected or not affected, apparently responsibility is presumably impaired. It is for the party alleging the contrary to prove it. Punishment of persons admitted to be insane for criminal acts has been advocated for the sake of the example. No good effect can be shown by a single case in point. Wrong as the present mode of procedure is, no change for the better seems very practicable, unless it may be that which takes the question of insanity entirely from the court and gives it to the jury as one exclusively of fact. The Section adopted, by unanimous vote, the following conclusions. 1. There is at present a manifest tendency to hold the insane responsible for criminal acts. 2. This tendency is unjust, unphilosophical, and contrary to the teachings of pathology, which clearly points out that insanity is but the expression of disease.

September 6.—SECTION I.—MEDICINE.

Do the Conditions of Modern Life favour specially the Development of Nervous Diseases?—Dr. Roberts Bartholow, Professor of Medicine in the Medical College of Ohio, quoted numerous references in the writings of the ancients to mental and nervous maladies, and spoke of the influence in ancient times of those conditions supposed to be most active in the present day in the production of nervous maladies, viz., social excitement, political revolutions, sexual excesses, indulgence in wine.

He mentioned the recognition of nervous maladies in the sixteenth century, and said that, if in modern times an increase in nervous maladies had occurred, the result must be exhibited to a limited extent in an increased sickness and mortality rate. With the improvement in the general well-being wrought by our modern civilisation, a manifest increase in longevity has occurred. With an improved hygiene, the sickness-rates and the mortality from epidemics have diminished. The supposed increase in the number of nervous diseases is more apparent than real. The art of printing has greatly increased the diffusion of knowledge amongst men, and hence every medical fact has not only a more prominent record, but is more generally known. In modern times, within this century especially, nervous diseases have been more accurately studied and better differentiated. The growth of a higher humanitarian sentiment has led to a more abundant provision for the insane.

SECTION III.—SURGERY.

The Medical and Surgical Treatment of Aneurism.—This subject was reported upon by Dr. William H. Van Buren, Professor of Surgery in Bellevue Hospital Medical College. The following conclusions were adopted. 1. Tufnell's treatment of aneurism by rest, position, and restricted diet, offers a valuable resource in thoracic and abdominal aneurisms. 2. It should always be tried in innominate, subclavian, subclavio-axillary, and iliac aneurisms, before resorting to measures attended by risk to life. 3. For aneurisms of the subclavian and iliac arteries, the Hunterian operation, with our present means of preventing secondary hæmorrhage, is not justifiable. 4. For reasons formally set forth by Holmes and Henry Lee, the 'old operation' cannot properly be substituted for the Hunterian operation in these cases, but should be held in reserve for special cases. 5. It is the most safe and surgical resource in gluteal aneurism, if the circulation can be commanded by the hand *in recto*. 6. The mode of cure by embolism, aimed at in the method of manipulation, is a not unfrequent explanation of what is called spontaneous cure of aneurism. 7. The value of Esmarch's bandage in the treatment of aneurism is probably not fully estimated. 8. In view of the promising features presented by the cases of Levis and Bryant, in which horse-hair was introduced into an aneurismal tumour, the repetition of this operation, or the substitution for horse-hair of Lister's prepared catgut or other animal substances, may be properly tried.

SECTION IV.—DERMATOLOGY AND SYPHILOLOGY.

The Virus of Venereal Sores; its Unity or Duality.—Dr. F. J. Bumstead, late Professor of Venereal Diseases at the College of Physicians and Surgeons, New York, stated the views held as to the origin of venereal sores, and presented the following conclusions, which were adopted with some modifications. 1. The virus of venereal sores is dual. 2. Venereal sores may be due to the inoculation of the syphilitic virus, and also to the inoculation of products of simple inflammation. 3. These two poisons may be inoculated simultaneously. 4 (additional). The present state of science has demonstrated that suppurating inflammatory lesions resembling chancroids may be produced on various portions of the body by inoculations with simple pus from various lesions.

SECTION V.—OBSTETRICS.

The Treatment of Fibroid Tumours of the Uterus. The subject was treated by Dr. Washington L. Atlee mainly from the standpoint of personal experience. Two principal divisions on the subject were stated:—1. Tumours usually accompanied with hæmorrhage, embracing (a) fibroids occupying the vaginal canal; (b) fibroids within the cavity of the uterus; (c) interstitial submucous fibroids; (d) interstitial fibroids proper; (e) recurrent fibroids. 2. Tumours usually not accompanied with hæmorrhage, including (a) interstitial subperitoneal fibroids; (b) sessile peritoneal fibroids; (c) pedunculated peritoneal fibroid; (d) interstitial cervical fibroid; (e) myomatous degeneration of the uterus; (f) fibrocysts of the uterus. The author considered the best mode of treatment both surgical and medicinal; the removal of tumours *per vias naturales*; and by abdominal section; the propriety of extirpating a fibroid uterus by either of these methods; and the several agents which are supposed to control the growth of fibroid tumours.

SECTION VII.—OTOLOGY.

In what Percentage of Cases do Artificial Drum-membranes prove of Practical Advantage?—Dr. H. N. Spencer, of St. Louis, after reviewing the history of the artificial drum-membrane, considered (a) the condition of the ear admitting of its use; (b) contraindicating conditions. He then took up (a) forms of artificial drum-membranes (under which head a preference was stated for Yearsley's cotton-wool); (b) the offices performed, functional and therapeutical. When the conditions are the most favourable, it was alleged that the cases are the fewest in number where the artificial drum-membrane will be worn, whether the reasons be objective or subjective. The Section then adopted the conclusions of the reporter, as follows. 1. Of the various forms of artificial drum-membrane in use, the cotton-pellet is preferable for its greater simplicity and its easier introduction, for the greater uniformity of its effect and the comparative safety in its employment. 2. It has an advantage over all other forms of artificial drum-membrane in that, additional to the functional gain which may be derived, there may be added its value as a means of treating the tympanum, and this therapeutical use of the artificial membrane has a great future in otology. 3. The continued use of the artificial drum-membrane as a means of improving the hearing is indicated in rare conditions which can only be determined by the aural surgeon.

SECTION VIII.—SANITARY SCIENCE.

The General Subject of Quarantine, with particular reference to Cholera and Yellow Fever.—The discussion was opened by J. M. Woodworth, M.D., Supervising Surgeon-General U.S. Marine Hospital Service. The following conclusions were adopted. 1. The supervision of ocean travel ought to be directed to securing good sanitary condition of vessels at all times, out of as well as in port. 2. A system of port sanitation should be adopted and administered for each country or place separately, modified in particular cases by taking into account the liability of the port to infection, the period of incubation of the disease, the length of time consumed in the voyage, and the measures enforced by the vessel *en route*. 3. In some countries the detention of passengers and crews of ships hailing from infected ports is warranted, but for such time only as

is necessary to complete the period of incubation of cholera or yellow fever, counting from the date of departure from an infected port or landing from an infected vessel, but in no instance should passengers or sailors be held for observation on board an infected vessel, and such vessel should not be detained beyond the period required for inspection and thorough disinfection and cleansing. 4. Recognising the fact that the modifications of infectious diseases may sometimes elude the most vigilant sanitary supervision of shipping, the importance of wisely directed internal sanitary measures can scarcely be overestimated. 5. So far as America is concerned, it is desirable that prompt and authoritative information should be had of the shipment of passengers or goods from cholera or yellow fever infected districts, thereby insuring the thorough disinfection of infected articles. 6. It is believed that the endemic forms of cholera and yellow fever are the fields which give the greatest promise of satisfactory results to well-directed and energetic sanitary measures, and to this end an international sentiment should be awakened, so strong as to compel the careless and offending people to employ rational means of prevention.

SECTION IX.—MENTAL DISEASES.

Simulation of Insanity by the Insane.—Dr. C. H. Hughes, of St. Louis, Missouri, read a paper on this subject, which he summed up in the following conclusion, which was adopted as the opinion of the section. It is not only not impossible for the insane to simulate insanity for a purpose in any but its gravest forms of profound general mental involvement, but they actually do simulate acts and forms of insanity for which there exists no pathological warrant that we can discover in the real disease affecting them.

September 7.—SECTION II.—BIOLOGY.

The Mechanism of Joints.—Dr. Harrison Allen, Professor of Comparative Anatomy in the University of Pennsylvania, read a paper on the mechanism of joints. 1. Starting with the idea that joints are of dynamic and static values, it was shown that in most movable joints the ball-and-socket arrangement predominates. When the ball is supported by the socket, as at the occipito-atloid articulation, rest is suggested. But when the ball is suspended from the socket, as at the temporo-maxillary articulation, motion is suggested. Dr. Allen illustrated the etiology of fracture and dislocation by reference to this method of study. 2. It was premised that articular surfaces are of three kinds—axial, actinic, and lateral. The axial or primary surfaces are those situated upon proximal and distal ends of a bone in the line of its longitudinal axis. The actinic or secondary (rarely seen) are those placed in a line which is deflected from the longitudinal axis. The lateral or tertiary are those situated upon the sides of the shaft or body of a bone and serve for articulation with corresponding surfaces of other bones—e.g., the outer femoral condyle is axial, since it is placed in the line of the longitudinal axis of the femur. The internal femoral condyle is actinic, since its line intersects the long axis of the femur, from which it may be said to be deflected. The lateral facets of the metatarsal or tarsal bones serve to illustrate the lateral kind. 3. Axial surfaces, it is believed, are static; actinic surfaces are dynamic; while lateral surfaces have subordinate degrees of

value—some of them being adventitious. The outer femoral condyle is active in extension—static; the inner femoral condyle is active in flexion—dynamic; but the lateral facets have no independent action. 4. Joints are fixed or locked at extremes of flexion and extension, and are most relaxed at the intervals between these extremes. An application of these premises was made to the etiology of dislocation. 5. When a facet is actively employed, it enters into a combination with which the entire limb is in harmony. Hence in the study of any one facet its relations to all others of its kind, as well as to the bones, muscles, and fasciæ of its limb, become essential. 6. A correct knowledge of the symptomatology and treatment of diseases of the joints is dependent upon a true conception of the complex nature of articular surfaces. The conclusions of the author were accepted by the section.

SECTION III.—SURGERY.

Treatment of Coxalgia.—Dr. Lewis A. Sayre, Professor of Orthopædic Surgery in Bellevue Hospital Medical College, described coxalgia, and divided the disease into three different stages, giving the symptoms in each stage. He then referred to the pathological changes in the joint in the three different stages of the disease, and to the etiology or causation of the disease. The following conclusions, after an animated discussion, were reported as the opinion of the section, with the statement that in conclusion No. 2 the section did not unanimously coincide. 1. Morbus coxarius is a disease most frequently met with in early childhood, or the age of reckless indifference. 2. It is almost always of traumatic origin, and not necessarily connected with a vitiated constitution. 3. Rest and freedom from pressure of the parts involved, while at the same time the rest of the body is allowed free exercise in the open air, and a nutritious diet, is the best treatment that has yet been devised for this disease. 4. If this plan of treatment be adopted in the early stages of this disease the majority of cases will recover, with nearly if not quite perfect motion, and without deformity. 5. In the advanced second stage of the disease, when absorption of the effused fluid cannot be produced, then it is better to puncture or aspirate the joint and remove its contents, than to leave it to rupture by ulceration. 6. In the third stage of the disease, when the treatment recommended has been properly applied without satisfactory improvement, but progressive caries continues, the excision of the diseased bone is not only justifiable, but in many cases absolutely necessary. 7. The operation of excision of hip is easily performed, and in itself attended with little or no danger. 8. After excision of the hip-joint in cases of progressive caries, the recovery is much more rapid and certain, and infinitely more perfect, as to form, motion, and the usefulness of the joint and limb, than when left to the slow process of nature.

The Causes and Geographical Distribution of Calculous Diseases.—Dr. Claudius H. Mastin, of Mobile, in treating this subject, gave a brief notice of the varieties and constituents of calculous concretions, tracing the formation and probable causes of gravel in the kidney, and afterwards of stone in the bladder. (a) Hereditary influences governing diathesis, with the effect of habit and mode of life upon the formation of these deposits. (b) Climate, food, water, and the default of exercise, as bearing upon healthy digestion and assimilation. (c) The influence

of age, sex, race, and occupation, and of moral and physical emotions; also the mechanical and traumatic causes of these affections. (d) The agency of the colloids in the formation of calculi. The author then gave a review of the manner of formation of gravel in the kidney, its passage through the ureter, and lodgment in the bladder; and an outline of the geographical sections in which calculous diseases are found to abound, with a summary of their probable causes.

SECTION IV.—DERMATOLOGY AND SYPHILOLOGY.

The Treatment of Syphilis.—Dr. E. L. Keyes, Adjunct Professor of Surgery and Professor of Dermatology in Bellevue Hospital Medical College, read a paper on the treatment of syphilis with special reference to the constitutional remedies appropriate to its various stages; the duration of their use, and the question of their continuous or intermittent employment. The following propositions, slightly modified from those originally presented, were adopted by the section. *Negative conclusions, views for which there would seem to be no foundation in fact.*—1. Syphilis commencing mildly needs but little treatment, and does not require mercury. 2. Mercury given internally is necessarily debilitating. 3. Mercury is only useful in secondary syphilis. 4. Iodide of potassium is of considerable value in secondary syphilis. 5. Iodide of potassium is of no value unless preceded by the use of mercury. 6. Iodide of potassium acts by liberating mercury which has been lying latent. *Positive conclusions, which, in the present state of our knowledge, may be affirmed.*—1. Mercury is an antidote to the syphilitic poison, and of service in controlling all its symptoms in all, even the latest stages of the disease; its power over gummata being least, and not to be relied upon. 2. Mercury in minute doses is a tonic. 3. Iodine cures certain symptoms of syphilis, but does not prevent relapses. 4. Mercury, long continued uninterruptedly, so far as practicable in small doses from the time of earliest eruption, constitutes the best treatment of syphilis.

SECTION V.—OBSTETRICS.

The Nature, Causes, and Prevention of Puerperal Fever.—Dr. W. T. Lusk, Professor of Obstetrics in Bellevue Hospital Medical College, after stating that puerperal fever is a generic term, defined its varieties and the distinction between non-infectious and infectious forms. The non-infectious form was described as the result of (a) Traumatic injuries; (b) Old peritoneal adhesions; (c) Disregard of hygienic precautions; (d) Mental influences. The infectious form, he stated, was a septic disease, and the local lesions were the usual though not necessary points through which the poison enters the system. He referred to the relations of bacteria to puerperal fever; the influence of erysipelas, scarlatina, diphtheria, etc., upon the puerperal state, and to atmospheric influences. As regards the causes, deductions were drawn from civil statistics, hospital statistics, and private practice, and in the prevention of the disease we must be guided by our knowledge of its causes.

SECTION VI.—OPHTHALMOLOGY.

Progressive Myopia and Posterior Staphyloma.—Dr. E. G. Loring read a paper on the question, Are Progressive Myopia and Posterior Staphyloma due to Hereditary Predisposition, or can they be induced by Defects of Refraction, acting through the In-

fluence of the Ciliary Muscle? The following were the conclusions. 1. From the fact that so large a percentage of children are myopic, whose parents are not near-sighted, while the myopia increases directly with the amount of increased tension of the eyes, and from the fact that an interchange of refraction may occur, whereby an eye which is not congenitally myopic may become so in spite of hereditary tendency against it, it would seem to follow that hereditary predisposition, though undoubtedly a potent cause, is not only not the sole cause, but it is not even the predominating cause. 2. The action of the ciliary muscle, taken by itself, exerts but little influence on the production of myopia, and still less on the formation of the cone. Of these conclusions, the first was adopted by the Section unanimously, and the second by a majority of fifteen to seven.

SECTION VII.—OTOLOGY.

The Hearing of School Children.—Dr. C. J. Blake, Instructor in Otology in Harvard University, read a paper on the question, What is the best Mode of Determining the Hearing of School Children; and how should Partially Deaf Children be instructed—in Mixed Classes with those who hear well, or in Separate Classes where due allowance will be made for their defective hearing? The following conclusions were adopted. 1. The frequency of partial deafness in children during the period of school life renders it advisable to make some definite provision in Public School Systems for compensatory instruction. 2. Since partial deafness is a comparative term, some provisions should be made for a proper determination of the degree of disability. 3. This is best accomplished either by establishing a series of speech tests to be used by the teachers, or by instituting competent medical examination at the hands of a medical supervisor of schools. 4. Partially deaf children, when hearing is not so defective as to require special instruction in articulation and lip reading, are better taught in mixed classes with those who hear well. 5. Partially deaf children, whose hearing is so defective as to interfere with the natural acquirement of articulation and to render the ear of little or no value as a medium for instruction, should be accorded the advantages of special instruction, of which instruction articulation and lip reading should form a part.

SECTION VIII.—SANITARY SCIENCE.

Disposal and Utilisation of Sewage and Refuse.—The discussion was opened by Dr. Henry Harts-horne, Professor of Hygiene in the University of Pennsylvania. The following conclusions which he offered were adopted. 1. Every plan for the laying out, or extension, of a city or town, should have as an indispensable part of it, a corresponding and co-extensive plan for the continuance or substitution of the natural drainage of the locality, and for the proper construction of a system of sewers. 2. The question in regard to the removal of waste and impurities from towns is not as to the maintenance of sewers, but as to whether they should be depended upon alone, or should be supplemented, more or less largely, by other means of conservancy. 3. Every sewer not supplied with a sufficient flow of water to secure the transportation of its contents is a nuisance, intensifying the evils it ought to remove. Ventilation of sewers will mitigate, but not entirely correct such evils. 4. Conditions sufficient for sanitary security are afforded by the discharge of sewage at a con-

siderable distance from a town, into the sea, or into a large and rapid river, whose water, at least for many miles below the exit of the sewers, is not used for drinking. 5. The earth-closet method of removal of excreta is, theoretically and practically, satisfactory in a sanitary aspect; the obstacles to its general adoption belonging only to economy and convenience. A supplementary proposition, affirming that the sewage-irrigation of arable land, well underdrained, is, where practicable, the most economical method of disposal of sewage, and is free from well-grounded sanitary objections, was not concurred in by the Section, which declined to express an opinion upon that subject, as still open to investigation.

SECTION IX.—MENTAL DISEASES.

The best Provision for the Chronic Insane.—Dr. C. H. Nichols, Physician and Superintendent of the Government Hospital for the Insane at Washington, gave the following conclusions, which were adopted by the Section. 1. Provision for the chronic insane should be made by constructing buildings in connection with the several hospitals for the insane. 2. It is not desirable to construct institutions solely for the care of the chronic insane.

September 8.—SECTION I.—MEDICINE.

Alcohol in its Therapeutic Relations as a Food and a Medicine.—Dr. Ezra M. Hunt, of Metuchen, New Jersey, summed up his paper in the following propositions, which were affirmed by the section. 1. Alcohol is not shown to have a definite food value by any of the methods of chemical analysis or physiological investigation. 2. Its use as a medicine is chiefly that of a cardiac stimulant, and often admits of substitution. 3. As a medicine it is not well fitted for self-prescription by the laity, and the medical profession is not accountable for such administration, or for the enormous evils resulting therefrom. 4. The purity of alcoholic liquors is not as well assured as that of articles used for medicine should be. The various mixtures when used as medicine should have definite and known composition, and should not be interchanged promiscuously.

SECTION III.—SURGERY.

Subcutaneous Division of the Neck of the Thigh-Bone.—Mr. William Adams, of London, read a paper on this subject. The following conclusions were adopted. 1. Bones can be divided subcutaneously like tendons; and that the operation of completely dividing the neck of the thigh-bone by a small saw, introduced through a small subcutaneous puncture, is a well-established surgical operation, attended with very little risk. 2. The long bones can be completely divided by the same method in any part of their length, with very little risk. 3. In a large proportion of these cases, the healing of the wound takes place by the first intention, and that no swelling, redness, or inflammation follows. These cases of subcutaneous osteotomy proceed as favourably as subcutaneous tenotomy. 4. In some cases a little suppuration from the track of the wound, amounting only to a few drops in the day, does occur for a week or more after the operation. 5. In a very few cases deep-seated suppuration occurs, but in only one of these, so far as at present known, has death resulted from pyæmia out of the twenty-three recorded cases. In one other case death was accelerated by the operation, or rather by the prolonged

suppuration which followed; the patient died eight months afterwards from albuminuria and phthisis. 6. The permanent result of the operation has hitherto generally been to correct the deformity and to obtain bony ankylosis with the limb in the straight position; but in several instances free motion has been obtained, and remained only for a few months, when it has been gradually lost. In a few cases free motion has remained for about a year, and we hope will persist through life, but time and further experience are necessary before this can be confidently stated to be a reliable result of the operation.

SECTION VIII.—SANITARY SCIENCE.

The Metrical System.—Dr. E. R. Squibb, of Brooklyn, submitted a paper on the Metrical System of Weights and Measures, and the following conclusions were adopted. 1. The metric system of metrology, though by no means faultless, is now by its almost universal acceptance practically inevitable; and, therefore, all means should be used whereby it may be gradually adopted, so as to avoid, as far as possible, the abrupt shock incident to its sudden and forcible introduction in the future. 2. The medical and pharmaceutical professions should be recommended to adopt the suggestion of giving the equivalent values of the old and new systems in their writings as an easy way of rendering them familiar in use. 3. The medical profession should be urged to use their influence in having the metric system introduced into the leading colleges and schools.

The following addresses and papers were also read.

General Meetings.—Address in Medicine, by Austin Flint, M.D., Professor of the Practice of Medicine in Bellevue Hospital Medical College.—Address on Hygiene and Preventive Medicine, by Henry J. Bowditch, M.D., President of the State Board of Health of Massachusetts.—Address on Medical Chemistry and Toxicology, by T. G. Wormley, M.D., Professor of Chemistry in Sterling Medical College, Columbus, Ohio.—Address on Surgery, by Paul F. Eves, M.D., Professor of Surgery in the University of Nashville.—Address on Medical Biography, by J. M. Toner, M.D.—Address on the Medical Staff of the United States Army and its Scientific Work, by Dr. J. J. Woodward, Surgeon U.S. Army.—Address in Obstetrics, by T. Parvin, M.D., Professor of Obstetrics in the College of Physicians and Surgeons of Indiana.—Address on Medical Jurisprudence, by S. C. Chaillé, M.D., Professor of Physiology and Pathological Anatomy in the University of Louisiana.—Address on Mental Hygiene, by John F. Gray, M.D., Superintendent Physician of the New York State Lunatic Asylum.—Address on Medical Literature, by L. P. Yandell, M.D., late Professor of Physiology in the University of Louisville.

Section I. Medicine.—The Etiology of Epilepsy, by Dr. W. F. Neffel.—The Influence of High Altitudes on the Progress of Phthisis, by Dr. C. Denison.—Treatment of Simple Ulcer of the Stomach, by Dr. H. Lebert.—Progressive Pernicious Anæmia, by Dr. B. Howard.—Sclerosis of the Vessels of the Lungs, by Dr. Rudneff.

Section II. Biology.—The Structure of the Sweat-Glands in Man, the Horse, and the Sheep, by Dr. Galani.—The Nerves and their Terminations in the Pleuræ of the Rabbit, the Dog, and the Cat, by

Dr. Leboeff.—The Microscopical Anatomy of the Nervous Apparatus of the Bronchi and Lungs in the Frog, the Rabbit, and the Dog, by Dr. Jantchich.—The Endings of the Nerves in the Skin of Man, by Dr. Jantchich.—The Occurrence of Fungous Growths in Solutions for Hypodermic Medication, and their Prevention by Salicylic Acid.

Section III. Surgery.—Penetrating Wounds of the Abdomen, by Dr. L. A. Dugas.

Section IV. Dermatology and Syphilology.—Leprosy, by Dr. F. H. Rodas.—What is the Disease known as Lupus? by Dr. Woskrijinsky.—The Unity or Duality of Venereal Virus, by Dr. C. R. Drysdale.—The Treatment of Seborrhœa, by Dr. C. Heitzmann.—The Treatment of Syphilis, by Dr. C. R. Drysdale.—Verrugas; a Disease peculiar to Peru, by Dr. G. C. Ward.—Measures to Prevent the Propagation of Venereal Diseases in Denmark, by Dr. S. Engelsted.—The Prevention of Syphilis, by Dr. C. R. Drysdale.

Section V. Obstetrics.—Management of Convulsions of Children depending upon a High Temperature of the Body, by Dr. T. K. Holmes.—Enucleation of the Ovarian Cyst, by Dr. J. F. Miner.—The Three most Important Obstetrical Instruments, by Dr. Lazarewitch.—Electrolysis, especially for the Cure of Ovarian Cysts, by Dr. F. Semeleder.—Paracentesis, Aspiration, and Transfusion, by Dr. Simon Fitch.—Uterine Hæmorrhage, by Dr. E. H. Trenholme.—Chronic Inversion of the Uterus, by Dr. J. P. White.—Retroversion of the Gravid Uterus, by Dr. T. F. Rochester.

Section VI. Ophthalmology.—Tumours of the Optic Nerve, by Dr. H. Knapp.—Statistics of the Condition of the Eyes of Scholars, by Dr. C. R. Agnew.—Orbital Aneurismal Disease and Pulsating Exophthalmia: their Diagnosis and Treatment, by Dr. E. Williams.—The Relations between Corneal Diseases and Refractive Lesions of the Eye, by Dr. G. T. Stevens.—Report of One Hundred Cases of Senile Cataract, by Dr. D. S. Reynolds.

Section VII. Otology.—Aural Vertigo with Variable Hearing, by Dr. C. H. Burnett.

Section VIII. Sanitary Science.—Vital Statistics of the City of Buenos Ayres, by Dr. G. Rawson.—Hospital Construction and Ventilation, by Dr. Stephen Smith.—The Preliminary Plans for the Johns Hopkins Hospital, by Dr. J. S. Billings, U.S.A.—An Universal Pharmacopœia, by Dr. E. R. Squibb.

Section IX. Mental Diseases.—On the Methods of Examination which will reveal a clear and decisive connection between the Symptoms of Insanity and the Pathological Lesions on which they depend, by Dr. E. C. Spitzka.

REPORTS OF FOREIGN SOCIETIES.

IMPERIAL ROYAL MEDICAL SOCIETY OF VIENNA.

May 5. *Malignant Lymphoma treated by Arsenic.* Dr. Von Winiwarter related a case in Professor Billroth's clinic, in which a remarkable result followed the treatment of a malignant lymphoma by arsenic. The patient, a man aged twenty-nine, said that in October 1874, after being stung by a wasp, he had swelling of the left axillary and cervical glands, and afterwards of the inguinal glands of the

same side. In the autumn of 1875 the glands of the right side began to enlarge, and he had dyspnoea and palpitation. On his admission on February 14, 1876, there was remarkable enlargement of the lymphatic glands of the neck, trunk, and upper limbs. The percussion-sound over the left half of the chest was dull; the heart was displaced to the right, and the spleen was considerably enlarged. The number of white corpuscles in the blood was not increased, and his nutrition was good. He was ordered to take Fowler's arsenical solution and tincture ferri pomati, five drops of each, every morning, the dose being increased by one drop daily. The largest daily dose of the arsenical solution in one day was forty-two drops; after this the quantity was reduced. There were no toxic symptoms. The result, as shown by a photograph, was very marked. The gland-tumours had in great part entirely disappeared, but some could still be felt. The dullness on the left side of the chest and the displacement of the heart still remained. The case was brought before the society, though still incomplete, as the man was leaving the hospital; but Dr. Von Winiwarter hoped that, under a continuance of the arsenical treatment, a permanent cure would be obtained.

On the Difference of Pressure between the Left Ventricle and the Aorta.—In order to test the opinion expressed in 1873 by Fick, that the pressure in the aorta was always greater than that in the left ventricle, Professor Stricker made a series of experiments on animals, and then employed a new method by which he confirmed his observations. He constructed an apparatus, of which the following is a description. A bulb constantly supplied with fluid (left ventricle) is connected with a tube, from which a branch protrudes perpendicularly (first manometer); this is provided with a valve, which, like the aortic semilunar valve, allows onward flow, but prevents reflux; from the more distant portion of the tube (aorta) arises perpendicularly a tube (second manometer), having attached to it a caoutchouc tube, the flow through which is regulated by a stop-cock. When the bulb is pressed rhythmically, the fluid rises in both manometers, but always stands higher behind the valve than before it. If the valve be held back, there is no difference in the height of the fluid in the two manometers.

The Human Ovum.—Professor Mayerhofer made a communication to contradict the hypothesis that the human ovary contains male and female ova. He said that if the man were older or stronger, and had coitus rarely, there was greater probability that a boy would be born; while, in the reverse case, the child would be a girl. Domestic animals (cows) impregnated at the beginning of heat, produced more female than male young; while, if they were impregnated at the end of heat, the reverse occurred. If it be correct that, among the orthodox Jews, who abstain from connubial rites during the menstrual period and for some days afterwards, more boys than girls are born, this may be explained by the fact that the ovum discharged from the ovary has already lost energy, is approaching abortion, and the woman can no longer impart her sex to it.

May 12. *A New Means of Diagnosis of Impaired Hearing.*—Dr. Albert Bing, in reading a paper on this subject, said that the cause of a high degree of deafness generally lay in inflammatory processes occurring in the mucous membrane of the tympanic cavity and their results. Among the latter were especially noticed impermeability of the Eustachian

tube, with anomalies in the tension of the chain of ossicles, inflammatory swelling of the mucous membrane, and collection of exudation in the tympanic cavity, and changes of a more persistent character in the ossicles. These changes are brought about by the growth, in consequence of inflammation, of connective tissue on the ossicles and on the walls of the tympanum. This product of inflammation undergoes changes, such as contraction and induration; the ossicles become abnormally adherent one to another and to the surrounding parts, and become rigid and ankylosed. In this way various degrees of impaired hearing, and even deafness, are produced. By the methods of examination hitherto in use, it has been indeed possible to ascertain the presence of resistance to the conduction of sound in the chain of ossicles; but it has not been possible to determine whether all or only one of the ossicles, and which, was affected, and which of them remained free. Dr. Bing believed that in the entotic use of the ear-trumpet he had found a fresh method of ascertaining whether the stapes was implicated, or remained more or less normal. By the entotic use, he meant speaking into the expanded end of the ear-trumpet, while the other end communicates directly with the tympanic cavity, a catheter having been introduced into the Eustachian tube. The author spoke further of the possibility of hearing through the Eustachian tube. On this point opinions were divided; the possibility being affirmed by Politzer and denied by Voltolini.

May 19. *On the Causes of the Occurrence of Convulsions in the Brain.*—Professor Meynert read a preliminary paper on a research which he had been carrying on for more than a year, for the purpose of ascertaining the cause of the cerebral convulsions, especially with reference to the idea already expressed by Halle, that they are produced through interference with the growth of the surface of the brain within the skull. According to this view the brain, if allowed to grow free outside the skull, would show other forms than when the retention of certain cranial axes opposes a resistance to the tendency to growth. The convolution thus produced must be developed in a direction perpendicular to the axes narrowing the brain. The origin of the convolutions from an interference with development is also supported by the thinness of the cortical substance within the sulci. The prosencephalon (*Vorderhirn*), if allowed to grow outside the skull and form a ball, would have straight sulci formed in it by arrest of development laterally, and sulci perpendicular to the others by interference with its growth in a direction from before backwards. Both these conditions should correspond with the production of dolichocephalism. In investigating the subject, Dr. Meynert made measurements of various skulls. In some animals he drew a line from the anterior edge of the ethmoid plate to the hindmost point of the upper angle of the petrous bone, and a transverse line passing over both external auditory meatus. In the human subject and monkey, the measurements used by Welker and Halle were employed. A comparison of the measurements of the skulls of the fox and dog with those of the cat and lion gives the following result:—

	Fox.	Dog.	Cat.	Lion.
Long diameter.....	100.0	100.0	100.0	100.0
Transverse diameter ...	77.0	85.0	97.2	98.7

These gradually increasing brachycephalic proportions correspond with stages of the development of the directions of the convolutions. The fox has the

relatively largest skull, and possesses a brain the sulci of which are almost purely longitudinal. In the dog there are transverse convolutions and transverse anastomoses; while in the cat-tribe, in which the skull is more quadrate, all the longitudinal sulci are interrupted by typical, almost perpendicular gyri, which form the anastomoses. In the seal and elephant the skulls are so brachycephalic that the percentage of the long diameter becomes negative:—

	Seal.	Young Elephant.	Old Elephant.
Long diameter	100.0	100.0	100.0
Transverse diameter	118.9	128.3	123.3

In the seal the compression of the long axis of the brain by brachycephalism as well as by compensation through an extraordinary height of the posterior part, not developed under the counter-pressure of the cerebellum, is expressed, through a perpendicular (instead of longitudinal) course of the olfactory lobes, by a perpendicular distance of an inch between the optic nerve and the olfactory bulb, as well as by the more remarkable phenomenon of a vertical Sylvian fissure. The convolution surrounding the Sylvian fissure is heart-shaped, through want of room for its development in the longitudinal direction. In the elephant's brain, the results to be expected from brachycephalism are to be found; viz., convolutions perpendicular to the long axis of the skull. Leuret pointed out more than thirty years ago that in this animal, instead of two transverse central convolutions as in man, there are three, and two central sulci in place of one. With regard to the brachycephalism of the quadrumanous skull, Dr. Meynert has convinced himself by the examination of five skulls (including those of the Chimpanzee and Orang) that the relations between the longitudinal and transverse diameters, observed in human dolichocephalism and orthocephalism, do not exist in the skull of monkeys, but only a strongly marked brachycephalism exceeding somewhat that of man. Similar relations to those above described have hitherto been found by Dr. Meynert in the measurement of skulls between the seventh and eighth months of foetal life. The gradations of convolutions in the animals above mentioned remain unchanged.

A Case of Cystin in the Urine.—Dr. Löbisch had examined the urine of a young American physician. It presented no unusual appearance, but always had an acid reaction, and the sediment contained crystals of cystin. He made analyses of the urine for fourteen days. In the literature of the subject, it is stated that cystin in the urine is always attended with diminution of the excretion of urea and uric acid. As cystin is a derivative of albuminous bodies, it must be assumed that the reduction of urea and uric acid can only be in proportion to the amount of nitrogen carried off by the cystin. On the other hand, sulphuric acid, which is regarded as a product of oxidation of the albuminates and of the decomposition of sulphates, may also be changed by the occurrence of cystin in the urine. As cystin contains sulphur, Dr. Löbisch determined on each of fourteen days the daily amount of urea, uric acid, cystin, and sulphates. The average result of ten days was:—urea, 33.28 grammes; uric acid, 0.4555; cystin, 0.3930. In this case, then, about four decigrammes (six grains) of cystin were excreted daily. The proportions of urea and uric acid were normal. The cystinuria produced no constitutional disturbance; but might at a future time lead to the formation of a cystin calculus.

May 26. *Morphiomania*.—Professor Leidesdorf, after remarking that several cases of morphiomania had been reported in the course of the past year, said that he thought that the relation of five cases which had occurred in his own practice would be of use as a warning against the too frequent use of the drug, and as a contribution to the knowledge of its physiological action. The first case was that of a lady, aged thirty-five, who for two years had suffered from the painful results of a perimetritis. Afterwards she herself injected morphia (as much as six grains for a dose), and fell off in health. The sudden withdrawal of the morphia was attended with considerable psychical irritation and severe diarrhoea; the patient, however, recovered in eight days, and was discharged cured four days afterwards. In the second case a man injected about $4\frac{1}{2}$ grains of morphia daily to relieve pain in the region of the spleen. He sold his Pravaz's syringe in order to deprive himself of the remedy, but could not wean himself from its use. The sudden withdrawal of the morphia was attended with persistent loss of sleep, with hallucinations, irritability, diarrhoea, and collapse. He was, however, discharged in a few weeks. The third case was that of a high official who injected $1\frac{1}{2}$ gramme (twenty-two grains) daily to relieve painful perostitis. He had profound melancholia, and attempted suicide. He was treated by baths and chloral-hydrate, and recovered; but relapsed and committed suicide. The fourth case was that of a man, aged thirty-one, who suffered from sciatica. Treatment at Gastein was not attended with success; and during four years he had used morphia in doses of thirty-seven grains subcutaneously, or forty-five grains internally. As the sudden withdrawal of the morphia produced alarming collapse, the quantity was gradually reduced; and under the use of chloral-hydrate, baths, wine, etc., he completely recovered in a few weeks. The fifth patient was a medical man, who wished to observe in his own person the effects of the use and disuse of morphia. He arrived at doses of twenty to twenty-five grains, became dull and sleepy, and could no longer do without the injections. Under the use of acetate of morphia he lost appetite, and had pains and abscesses; on many occasions (perhaps from injection into the veins) he had congestion of the head, difficulty of breathing, and formications over the whole body, lasting several seconds. After unsuccessful attempts to desist from the habit—sensitivity being greatly increased by the sudden withdrawal of the morphia—a cure was effected in eight weeks by the gradual reduction of the quantity, until total abstinence from the drug was arrived at. The patient must be entirely under the control of the physician, as deception is otherwise certain; all the patients had their syringes and a supply of morphia for several weeks. A careful watch must be kept during the treatment (eight or ten days) to prevent attempts at suicide. The cure is aided by the use of wine, warm baths, and chloral hydrate.—Dr. Eisenschitz related a case under his observation, in which both the patient and the physician made repeated attempts to stop the practice, but without success. The daily dose was 15 decigrammes ($2\frac{3}{4}$ grains). The patient, a man aged sixty-seven, became stupid and almost completely lost speech. By persuasion, restraint, watching at night, the use of chloral-hydrate, etc., Dr. Eisenschitz succeeded in entirely stopping the use of the drug. During the first thirty-one hours of the treatment the patient

took no food, was irritated during seven or eight days, and had severe diarrhoea.—Dr. Winternitz said that, in cases of morphia mania, the lowering of the temperature by baths of 68° to 77° Fahrenheit was borne ill or not at all; while, on the other hand, the application of hot cloths along the cervical spine had some effect in reducing the desire for morphia.

June 2. *Tumour of the Alveolar Processes*.—Dr. Weinlechner showed a young woman aged twenty, who had a morbid growth on the alveolar processes of the upper and lower jaws. It was lobulated, very firm, and after removal presented on microscopic examination the characters of fibro-enchondroma. The right half of the lower jaw was excised, and the growth was removed from both upper maxillary bones by the hammer and chisel.

June 9. *Catheterism of the Ureter*.—Dr. Grünfeld described the attempts made by Tuchmann and Simon of Heidelberg, to reach the vesical opening of the ureter. While the former laid hold of the mouth of each ureter in a man by means of an instrument like a lithotrite, the former performed rapid dilatation of the urethra in a woman, and guided a catheter into the mouth of the ureter along his finger. The method followed by Dr. Grünfeld differed from these in the following respects; that the operation was performed with a full bladder, and under the control of the eye. The vesical orifice of the ureter was first sought out by means of a fenestrated endoscope. This was generally attended with no difficulty. When the instrument reached the inner border of the orifice of the urethra, it must be inclined at an angle of thirty to thirty-five degrees from the meridian plane of the body towards the side, and the outer end must be held upwards and outwards. On now pushing the endoscope two and a half or three centimetres into the bladder, the orifice of the ureter often comes into view at once; if not, a few manipulations will discover it. The sound to be introduced into the urethra is carried into the bladder along with and parallel to the endoscope. Dr. Grünfeld had a sound constructed, which could be bent by a simple mechanism at one or two centimetres from the end, and again straightened. The operation is performed in the following way. The orifice of the urethra is first discovered by means of the endoscope. The urethral sound is now introduced into the bladder along the side of the tube (on the left side when the right ureter is to be reached, and *vice versa*). The lower end of the sound is now bent at a right angle, so as to meet the field of vision of the endoscope. If the proper direction have been given to the end of the sound, it is carried with an equable pressure along the base of the bladder into the orifice of the ureter. A few attempts are sufficient to make it enter. When it is seen with the endoscope that the sound has entered as far as the joint, it is straightened (care being taken lest it slip out), and is pushed on into the ureter. As yet, Dr. Grünberg had operated only on women, in whom the discovery of the opening of the ureter was not attended with the same difficulty as in men. He had only used a sound; but the introduction of a catheter ought to be attended with no difficulty.

Cranial Tumours in a Child.—Dr. Weinlechner communicated the particulars of the case of a boy, aged two, who had on the right parietal bone a tumour nearly as large as a fist and a half; it was divided into a larger posterior and a smaller anterior portion. The posterior part of the tumour was punc-

tured, and two ounces of fluid, having the chemical character of cerebro-spinal fluid, escaped. Dr. Weinlechner afterwards ascertained that it was of traumatic origin, and that the case was one of meningocele, or, more correctly, of hydrocele of the brain. When the case was brought before the society on a previous occasion, Dr. Rokitsansky expressed the opinion that the sac was a secondary formation, which could scarcely communicate with the interior of the brain. Dr. Weinlechner subsequently punctured the anterior part of the tumour: when, after penetrating to the depth of an inch, cerebro-spinal fluid was evacuated. Twenty-four hours after the operation the child appeared well; but at the end of thirty-six hours symptoms of meningitis appeared, and death took place on the eighth day after the operation. At the *post mortem* examination, which was made by Dr. Kundrat, there was found a sac lined with pus, and having two openings, one leading into the brain, the other into the subarachnoid space. The anterior part of the tumour was an encephalocele, the posterior a meningocele. The injury had affected not only the right but the left parietal bone, in which an united fissure about three inches long was found. In the second operation the lateral ventricle had been punctured, and this gave rise to the meningitis. Dr. Weinlechner also referred to four other cases, all in children, in which injury was followed by the formation of cystoid swellings, containing cerebro-spinal fluid. Two of those cases were observed by himself, one by Dr. Billroth.—Dr. Rokitsansky thought that the swelling had its origin in a large extravasation between the pericranium and skull and between the skull and dura mater, which was lacerated at one part.

June 16. *The Treatment of Diseases of the Nose.*—Dr. Catti showed gelatine bougies charged with various medicines—sulphate of copper, sulphate of zinc, tincture of rhatany, carbolic acid, etc.—for use in diseases of the nose. They were from 3 to 4½ inches long, and from 0·15 to 0·25 inch long, thicker at one end than at the other. The bougie, held at the thin end, was introduced into the nostril, and carried onwards by rotatory movements. It might be introduced into either the lower or the middle nasal fossa, or quite vertically. When it had entered the nasal passages, it could be seen by the rhinoscope between the septum and the lower turbinated bone, or between the middle and lower turbinated bones. If it reached more than a few millimètres into the naso-pharyngeal space, its harder end must be drawn forward and a portion cut off, otherwise it was liable to pass into the fauces or mouth. After the operation, the nostril was plugged with charpie. In two or three hours the bougie was completely dissolved. Dr. Catti had obtained good results from this treatment in daily practice for some time in cases of chronic nasal catarrh, naso-pharyngeal catarrh, hypertrophy of the tonsils, and ozæna. All the patients bore the treatment well.—Dr. Roth had for some time used gelatine bougies in diseases of the nose. He preferred conical bougies, which filled the nostrils better. In a case of severe epistaxis, he had obtained excellent effect from this method.

Retained Fœtus in an Old Woman.—Dr. Chiari showed the organs of a woman, aged eighty-two, who died in the General Hospital of pneumonia some days previously. During life, a tumour of the size of a man's head could be felt in the hypogastric region; it was connected with the uterus. The patient had

noticed the swelling since 1827, after her last pregnancy. At that time she felt herself to be pregnant; but, after eight months, no labour came on, and from this time she constantly had the abdominal tumour, which was unattended with pain, and on account of which she never had medical advice. The uterus was very large, and with its appendages on the right side were quite normal. On the left, there was a Fallopian tube five inches long, but the ovary of that side could not be found. The tumour was connected with the uterus, to which it was adherent, and also to the omentum and to the peritoneum in Douglas's pouch. It was about seven inches long and six inches broad, and in some parts had a hard, at others a soft feel. On laying open the tumour, it was found to contain an encapsuled fœtus. The section revealed distinctly the face, spinal column, internal organs, and the umbilical cord, which passed into a structure which on microscopic examination was recognised as a placenta. Of the extremities, all were found except the left arm, which might have become incorporated with the membranes when the change of position of the fœtus took place. The structure of most of the other organs could not be made out; and they contained deposits of lesions, fat, pigment, and especially of lime-salts. The muscles of the skeleton were in the best state of preservation; the striæ could be distinctly seen in them.—Dr. W. Schlesinger related the particulars of a case of retention of a dead fœtus in the abdominal cavity of a woman whom he had under observation during two years. The patient was aged thirty-four. Her first delivery, a normal one, took place fifteen years ago, she believed herself to be again pregnant. In the course of her pregnancy, she had extraordinary distension of the abdomen, the breasts became turgid and colostrum occasionally escaped, and she said that the movements of the child were very distinct. In July, 1874, in the ninth lunar month of her pregnancy, some pains as of labour set in. Labour, however, did not take place; but the pains increased, and on the third day she felt as if a laceration of something in her abdomen had suddenly occurred. From this time the distension from which she had suffered ceased; and the only symptoms for some weeks were those of moderate peritoneal irritation. There was no hæmorrhage during the pregnancy; but some days after she had the labour-pain, there was a discharge of blood which lasted nearly six weeks. When Dr. Schlesinger first saw her, in the beginning of September, the abdomen was as large as at the full term of pregnancy, though irregularly distended; it had a uniformly hard and smooth feel, as if it contained a solid tumour. At one part alone, four finger-breadths above the umbilicus, at the middle of the upper limit of the tumour, a protuberance like a finger-joint was felt. At the right side, the swelling extended as high as the ribs, but not so high in the middle as on the left. Immediately above the symphysis pubis, the abdominal integuments could be pushed in to some extent between the bone and the tumour. The latter, however, was but slightly movable. There was very little tenderness on palpation of the abdomen; but pressure on the tumour in the right hypogastric region (where the patient had from the first complained of pain) produced discomfort. Percussion over the tumour gave a hollow sound everywhere. Nothing could be heard on auscultation. Vaginal examination showed that the vaginal portion of the

uterus was strongly directed backwards and drawn up; the anterior vaginal vault was somewhat pressed on, but not quite filled with a body, which appeared to have no direct connection with the swelling felt above (anteflexion of the enlarged uterus). There was an abundance of milk in the breasts; no fever. The patient complained principally of pains in the right side of the abdomen, which became worse in the evening especially, and prevented her from lying long on the left side. There was very little sanguineous discharge. Subsequently to this, measurements made at intervals of two or three months showed a steady decrease in the circumference of the abdomen; and at the same time portions of the tumour acquired a softer feel. In speaking of the differential diagnosis, Dr. Schlesinger said that the case might be supposed to be one of rapidly growing fibroid of the uterus or ovary, but that the etiological history and the course of the case opposed this supposition. The woman had menstruated regularly during the last year and a half, had no abnormal discharge of blood, and her general health was good. The case, Dr. Schlesinger believed, was probably one of primary abdominal pregnancy.

On the Constancy of a Convolution in the Temporal Lobe.—Dr. Heschl described a convolution which he had found to be of constant occurrence, lying transversely on the surface of the temporal lobe, in a direction from within outwards. It had already been seen by many, and was figured by Heule; but no notice had been taken of it by other authors. Dr. Heschl's researches had proved to him that this convolution is the most constant and most early in appearance of all the cerebral convolutions. There are in many cases three such convolutions, in others two; but the one first referred to is constant. It is from 4 to 4½ centimètres long. It is sometimes divided by a notch; sometimes has a peculiar transverse division, showing a narrow base, and a round, indented, or angular surface. It always proceeds from the upper temporal convolution, generally by two roots; but sometimes the first temporal convolution passes into it in an arched form. Dr. Heschl's researches have further shown that this is the first convolution which can be observed in the fœtus. Indication of its appearance may be seen as early as the fifth or sixth month.

ACADEMY OF MEDICINE IN PARIS.

Sept. 26. *Movements of the Spine.*—M. J. Guérin read a memoir on the flexion and inclination movements of the vertebral column. The lateral movements of the spine present for consideration from the base to the summit:—1, an inclination movement of the entire column on the sacrum; 2, a flexion movement at the level of the eleventh and twelfth dorsal vertebrae, or of inclination of the dorsal on the lumbar region; 3, an inclination movement of the whole of the cervical region on the dorsal region; 4, an inclination movement of the head on the extremity of the cervical column; 5, a lateral flexibility decreasing above each of these three points, and a rigidity decreasing above them.

Oct. 8. *Feeding of Children.*—M. Magne read a memoir on the suckling and weaning of children and young animals. He asked why artificial feeding, so favourable to young animals, is generally regarded as disastrous to children; why solid food, added to

milk, or even substituted for it, which are advantageous to cats and calves, are hurtful to infants? He did not agree with the opinion which prescribes that infants should be fed on mother's milk until they are a year old, and that after that time they should be fed on bread and milk, rice-milk, etc. These latter foods appeared to him insufficient to take the place of milk, and milk itself is insufficient for children from seven to ten months old. They require larger proportions of phosphates and albuminoid substances than during the first months of life for the requirements of ossification and muscular development, and the mother's milk cannot during twelve months increase in the proportion of the wants of the nursing. M. Magne had often ordered raw eggs for children from eleven to twelve months old not able to walk, and after several days of this regimen they had acquired enough strength to walk alone. Breeders of young animals who have modified the system of training them, and wean the young ones very quickly, obtain incomparably better results. According to M. Magne, the prejudice which exists against the artificial nursing of children and the substitution of more substantial and less watery foods for milk is an unjust one. It is by artificial feeding, commenced from birth, with the addition of linseed and oil-cake, that breeders obtain those finely shaped bulls and powerful horses which gain the prizes at shows and races. The more compact is the composition of an aliment, the more nutritious it is. We should not try to improve natural products for children by disengaging their quintessence; we should not give the suckling infant superfine flour or grits, or oatmeal, but the whole grain, comprising the bran and the husk. More meat should be used in the alimentation of the suckling babe, and that not only in the form of juice or extract of meat. To sum up, raw eggs, chopped boiled eggs, meat, flour, and leguminous vegetables, should, according to M. Magne, enter largely into infant diet.—M. Bouley charged M. Magne with establishing an inaccurate comparison between the herbivora and the carnivora; the herbivora have the faculty of seeing and walking at the time of their birth, which shows that they can live an independent life and dispense with the mother's milk sooner than the carnivora. It would therefore be dangerous to conclude that what occurs with the herbivorous nursing is useful for the human infant.—M. Depaul entirely coincided with these views, and called to mind that it is precisely by substituting in a hasty manner alimentation by broth, eggs, etc., for mother's milk, that the mortality of early infancy is increased in a formidable proportion. Besides, infants do not die only because they are badly nourished, but because they are scantily clothed, exposed to cold, and placed under unhealthy conditions.

Oct. 10. *Feeding of Children.*—MM. Devilliers, J. Guérin, and Marotte, returning to the question of the artificial feeding of new-born children, protested against the hasty and dangerous conclusions formulated by M. Magne on purely zootechnic data.—M. Magne, disavowing any competency in the matter of the treatment of children, acknowledged that he had been advocating a bad cause.

Foreign Body in the Oesophagus; External Oesophagotomy.—M. Cazin, of Boulogne, read a case of this kind, in which he insisted on the following points. 1. The method of dissection of the lateral lobe of the thyroid, advocated by Duplay, was rendered more laborious in this special case by the existence

of a goitre. 2. It is well to have recourse to the separate suture of the two layers of the œsophagus, so as to ensure coaptation, and to place the internal suture out of danger of contractions of the muscular layer. 3. The sound (introduced by the nostrils) should be left *in situ* as long as it can be borne.

ACADEMY OF SCIENCES IN PARIS.

Aug. 21, 1876. *Bacteria*.—M. Bastian replied to M. Pasteur that the cause of the negative result of his experiments is not the temperature of the boiling, but the addition of potash in excess. He maintained that the temperature of fifty degrees Centigrade is very liable to bring on the spontaneous generation of bacteria, and that potash in excess completely destroys the germs of these parasites.

Sept. 11. *Trephining*.—M. Sédillot communicated a paper on preventive trephining in fractures with displacement of splinters of the internal or vitreous table of the cranium. The author, in his former communications (*Comptes rendus* of Oct. 12 and Nov. 16, 1874, tome lxxix.) on the fractures of the internal or vitreous table of the cranium with displacement of splinters, had demonstrated that trephining is the only method of preventing inevitable and nearly always mortal complications. The present paper contained one hundred and six confirmatory cases, partly derived from the publications of MM. Chauvel, Gross, Cochu, T. and J. Boeckel, and Schalk, and several from M. Sédillot's own experience. Out of the one hundred and six wounded, seventy-seven were trephined; twenty-nine were not operated on; nine trephinings were preventive—that is to say, they were performed before the appearance of primitive or consecutive accidents. After the first day sixty-eight curative operations were done with the object of remedying grave complications, such as paralysis, loss of consciousness, convulsions, coma. Amongst these twenty-one operations were performed in the first five days of the wound, and forty-seven were delayed until after that time. Out of a hundred wounded patients the external table of the cranium was found unfractured in twenty-one cases; and as the majority of the patients at first showed in few symptoms, their wounds were frequently thought to be but slight. Out of the twenty-nine wounded suffering from vitreous fractures with splinters not trephined, there were one cure and twenty-eight deaths; out of the seventy-seven trephined, twenty-nine cures, eighteen deaths. Nine preventive trephinings gave six cures and three deaths; sixty-eight curative trephinings gave twenty-four cures, forty-four deaths; twenty-one early trephinings, eight cures, thirteen deaths; forty-seven retarded operations, fifteen cures, thirty-two deaths. These results, according to the operator, were the confirmation of the facts and precepts laid down in his preceding communications. The mortality was in proportion to the delay in the application of the trephine; two-thirds of the patients were saved by preventive trephining; more than a third by early trephining; less than a third by retarded trephining, and only one in twenty-nine in the cases where recourse was not had to trephining. M. Sédillot reminded his audience that he had proposed, in cases of doubt or hesitation as to the existence of a vitreous fracture, to have recourse to explo-

rative trephining which Dr. Gross, of the Faculty of Medicine of Nancy, had performed under very bad conditions of general health. This operation was performed for the first time, and will certainly be again attempted. The patient, it is true, died, but death must not be attributed to the laying bare of the diploë. The suppurated state of the dura mater showed that it had received an indirect contusion, and the uncovering of the diploë does not usually bring on accidents, as we see in superficial excisions of the cranium by sabre-wounds. Surgical removal of a bony fragment of the fractured external table does not cause contusion of the diploë, divided and laid bare, in all the applications of the trephine. Therefore it is allowable to renew this attempt. M. Sédillot also analysed ten cases of trephining to demonstrate the fact that complication of vitreous fractures, the time elapsed after the wound, the circumstances under which the wounded are placed, and their degree of vitality, have a great influence on the condition of the patients who succumb quickly to, or resist in a surprising manner, nearly identical lesions.

Oct. 9. *The Flow of Blood through small Tubes*.—M. Haro presented a note on the flow of blood through tubes of small calibre (Graham's transpirability). Having constructed a special apparatus (the transpirometer) the author endeavoured to determine the degree of viscosity of the blood. The results obtained were as follows. 1. Heat greatly accelerates the flow of defibrinated blood, and this effect is the more decided according as the blood is richer in corpuscles, whilst heat acts upon serum almost in the same way as on distilled water. M. Haro has also remarked that this action is much more decided when the flow of the defibrinated blood is very slowly effected through a very contracted tube. The course of the blood in the capillaries of the organism being much slower than the artificial flow of the defibrinated blood, the rapidity of the circulation in these small vessels would necessarily, under the influence of temperature, show considerable divergences. The experimenter has also observed that defibrinated blood through which a current of carbonic acid gas has been passed for some length of time, and which has afterwards been filtered through a fine cloth, to remove all the gaseous bubbles, flows more slowly than the same blood reddened, by changing from vessel to vessel in the open air; under the influence of this gas the transpirability of calf's blood rose from 5,612 to 6,076. The author also stated that sulphuric ether not containing a trace of alcohol retards the flow of defibrinated blood, serum, and water. This result is the more surprising from the transpirability of ether being represented by the number 0,299—that is to say, this liquid flows three times as quickly as water. Chloroform retards the flow of water and serum, whilst it accelerates the flow of defibrinated blood. This double action, which at first sight seems paradoxical, is however very rational; thus, on the one hand, there is nothing astonishing that chloroform, of which the transpirability is from 0,396 to 15 degrees, acts on the water in an analogous manner to ether—that is to say, by slackening the flow. On the other hand, the liquid facilitates the passage of defibrinated blood through the capillary tube. This fluidification of the blood may explain the frequency, and especially the weakness, of the pulse produced when inhalations of chloroform are unduly prolonged.

REVIEWS.

Lectures on Orthopædic Surgery and Diseases of the Joints. By LEWIS A. SAYRE, M.D. 471 pages. 274 illustrations. Published by D. A. Appleton and Co., New York; and J. and A. Churchill, London. 1876.

In the historical sketch which follows the introductory lecture, the first performance of tenotomy in America is attributed to Dr. David S. Rogers in 1834. Two years elapsed before it was performed in England.

The five next lectures, covering thirty-eight pages, embrace the subject of Deformities. Dr. Sayre relates three cases of what he calls 'reflex paralysis' dependent on 'congenital phimosis and adherent prepuce,' and one case of 'threatened chorea cured by removing supernumerary toes and fingers,' which were a burden to the possessor's mind. The plates of the feet and hand after operation are, to say the least of them, flattering, for no amputation scars are anywhere visible.

In speaking of the principles of treatment of deformities, Sayre gives a law by which the surgeon may determine whether the case does or does not require operation. 'Place the part contracted as nearly as possible in its normal position, by means of manual tension gradually applied, and then carefully retain it in that position; while the parts are thus placed upon the stretch, make additional point-pressure with the end of the finger or thumb upon the parts thus rendered tense; and if such additional pressure produce reflex contractions, that tendon, fascia, or muscle must be divided, and the point at which the reflex spasm is excited is the point where the operation should be performed.' If no reflex contraction occur, no operation is indicated. Constant elastic tension should permanently overcome such deformity.

On the important question of the immediate after-treatment of cases operated on, Dr. Sayre pronounces strongly in favour of restoring the deformed parts at once as nearly as possible to their normal position. He admits some exceptions; for instance, in all cases of fibrous ankylosis producing articular deformity in which section of the contracted parts becomes necessary, the external wounds are to be permitted to heal before force is applied to break up the ankylosis. Formerly, he belonged to those who taught that the limb was to be secured in its deformed position until the external wound had closed, and the inflammatory action had subsided. The propriety of allowing the severed ends of tendons to be cemented together, and of gradually stretching the bond of union at a suitable period after operation, is not discussed. The writer contents himself with giving the result of his experience in a positive form. We are not informed whether, in his cases of tenotomy, the ends of the severed tendons are reunited or acquire new peripheral attachments at a distance from each other. In lecturing on talipes from spastic and paralytic causes, he teaches that the deformity is to be overcome as far as possible immediately after operation, and the limb secured in a natural position.

We are glad to find that the author strongly insists on the propriety of commencing treatment in cases of talipes immediately after the birth of the infant. He is an advocate of the principle of elastic

extension practised in cases of talipes by Mr. Barwell. (He fully describes this mode of treatment, quoting Mr. Barwell's own account of it.)

His observations on electricity, manipulation and 'massage,' dry heat, baths, inunction, and gymnastics, are not such as to require any special notice. Of medicinal agents, he praises strychnia, and refers to the subcutaneous injections of this drug; but, as he does not enter into details, our knowledge of the subject has not been advanced.

Having now afforded his class a general outline of the subject, he commences the seventh lecture with a study of special deformities. Talipes is first spoken of. In describing the mechanical construction of the normal human foot he states here, and in the lecture on Diseases of the Ankle-joint he repeats it, that at the tibio-tarsal joint or ankle any lateral movement is prevented by the projecting malleoli on each side, which fit so closely to the sides of the astragalus as to permit no motion at the joint except those of flexion and extension, or of pointing the toes up or down. Turning the toes out or in is produced by rotation of the toe and leg at the hip-joint, or by the revolving motion of the fibula produced by the contraction of the biceps and tensor vaginæ femoris when the knee is flexed. Now, this is not absolutely and entirely the case. The posterior part of the astragalus is narrower than the anterior. When the toes have been pointed downwards, the narrower part of the astragalus has been brought between the malleoli. The consequence of this is, that the astragalus can now move from side to side, and the toes may be directed inwards or outwards, and some lateral movement imparted to the whole foot.

Farther on, when he is speaking of the pathology of talipes valgus in its acquired form, he attributes it primarily to paralysis of the tibialis anticus muscle. Projection of the head of the scaphoid bone is mentioned, but no reference is made to the head of the astragalus or to the condition of the calcaneo-scaphoid and other ligaments, which must have yielded and stretched as the deformity progressed. Dr. Sayre holds strongly to the opinion that most cases of congenital talipes are paralytic in their origin rather than spastic, and appears to found his belief on the great ease with which he can, when examining the infant immediately after birth, restore the foot nearly or quite to its normal position.

In the tenth lecture, after having specially described the treatment of talipes by manipulation, roller bandage, gypsum bandage, gutta-percha and leather splints, plaister, and the elastic extension apparatus of Mr. Barwell, he makes this very important observation. 'The permanent fixing of any limb or joint in a stationary apparatus, thus preventing even the healthy muscles from contraction and relaxation, will sooner or later cause even these muscles to become atrophied and undergo fatty degeneration.' He strongly deprecates the use for any length of time of any form of appliance which shall prevent or materially limit the proper movements of the foot. Dr. Sayre's experience has been similar to that of most surgeons. 'Unfortunately,' he says, 'the great majority of cases that fall under our care require tenotomy, and almost without exception require such operative interference, simply because a rational method of treatment has not been put in practice early in their history.'

After tenotomy, he insists that the deformity is to be overcome as far as possible and the foot restored

to its normal position, and as soon as the wound has healed (a week to ten days) passive movements are to be commenced.

In bad cases of talipes varus and equino-varus, it commonly happens, after suitable tenotomy and restoration of the foot to its normal shape, that there remains a tendency on the part of the whole limb with the foot to invert. Reynders, the instrument-maker, has recently made for Dr. Sayre an apparatus for overcoming this rotation. It seems useful and simple. Our own instrument-makers try to meet the difficulty by fixing the leg-iron into the sole of the boot at an angle. Reynders' instrument appears to afford the advantage of a power of graduating the angle by a screw. For double talipes he describes separating rods, which are to keep the feet apart and everted.

The next fifteen pages are occupied by a lecture on bunions, corns, ingrowing toe-nails, bow-legs, and knock-knee. Amongst these he describes an interesting case of displacement of the tendons about the ankle-joint.

The lectures on Diseases of Joints, to which we have looked with some interest, cover 207 pages. We soon meet with topics which arrest our attention. We pass by a repetition of his view of the anatomy of the ankle-joint, and stop at the etiology of joint-disease. Sayre will not allow that the origin is in scrofula. He states, 'There is no scrofula about it in the vast majority of cases.' This statement contains an admission that the diseases are scrofulous in some cases, but he does not go farther, as we think he should have done, so as to draw the distinctions between the diagnostic signs and symptoms of the white swelling non-scrofulous and white swelling scrofulous. He does not even lay down a definition of what he understands by scrofula. If in his mind scrofula be synonymous with tubercular disease, then he is right to deny that joint-disease is commonly scrofulous in its origin. We think it must be admitted that the disease known as white swelling is distinctive in its signs and symptoms. These latter differ from those of synovitis, and of syphilitic, rheumatic, and gouty diseases of the joints. They commonly commence in early years, before the age of fifteen, when scrofulous diseases prevail. They do not commonly begin after that age. On the other hand, we meet with children suffering from chronic disease of the joint, which has not at any time in its history presented white swelling. We are not prepared with a new classification of diseases of joints, but we cannot agree with those surgeons who make the sweeping statement that diseases of joints commonly designated scrofulous are traumatic in origin rather than specific. We would prefer such a classification as Dr. C. Hueter gives in his work on Joint-Diseases (1871).

Dr. Sayre traces back the origin of articular diseases to traumatic lesions, and especially to what he calls a 'blood-blisters.' By this he means a small quantity of blood effused behind the synovial membrane, or between the cartilage and bone. From this centre he traces the spread of disease through inflammation, suppuration, caries, and necrosis. We should have felt better satisfied on this point, if he had supported his theory by a report of a *post mortem* examination of one of the so-called 'blood-blisters.' We do not deny that arthritis commences from such a lesion. We do not deny that injury is commonly the starting-point of a joint-inflammation; but until pathologists—he and others—have clearly

established the want of connection between the peculiar progress of such cases as those of white swelling of joints and the scrofulous diathesis, we must adhere to our opinion that the peculiar course taken by these cases is governed by a special condition of general health. This question of scrofula is discussed again and again in the lectures on diseases of the various joints, especially the knee and hip, but only to emphasise the author's view that the scrofulous state is the result of the arthritic disease, and not the cause. We nowhere meet with any definition of the term.

Elastic compression is advocated by the author as the suitable early treatment of synovial effusions into the ankle, knee, and similar joints. The pressure should be uniform, and made with the aid of sponges and bandage, or double India-rubber bags. Dr. Sayre demonstrated the mode of applying these when he visited London in 1871. The class of cases demanding such treatment is that of bruises and sprains, which involve the synovial membrane, and are followed by effusion and over-extension.

At page 165, in the course of the lecture on Diseases of the Ankle-joint, we meet with an extraordinary statement that you cannot 'exsect' the joint unless by transverse incisions which must cut across muscles and nerves. He goes on to mention a plan of setoning, as if no such operation as that described by Mr. Hancock had ever been performed. We do not doubt that oakum setons are successful; but, judging by the cases mentioned, the plan is a very tedious one, and may have to be repeated more than once. Here it is convenient to notice a statement of an opinion with which we cordially agree, that the long-continued use of hot poultices to swollen and suppurating joints is always injurious.

The mode of examining joints is everywhere most practical and ingenious.

He admits that cartilage is not supplied with nerves, and yet he states that when inflamed they become exceedingly sensitive, but what proofs he possesses of this we are not informed.

We know no author who so satisfactorily explains the phenomena of nocturnal pains in joint-diseases.

As might have been expected, the symptomatology of Hip-joint Disease is very fully and ably detailed. This part of the lectures will be read with great interest. Without defining what he means by dislocation, he denies at considerable length that the head of the femur ever becomes dislocated except by accident; to use his own words, 'instead of a luxation of the hip, we have in fact a displacement of the acetabulum.' He adds, 'As long as the acetabulum retains the remnants of the head of the femur within its cavity, it should not be called luxation of the femur.'

In reviewing the treatment of diseases of the knee and hip-joints, besides the elastic compression recommended for the knee, we notice that the advantages and disadvantages of the aspirator have not escaped his attention. Nor does he omit to call especial attention to 'pressure on the main trunk of an artery leading to any part in danger of inflammation, in such manner as to diminish the supply of blood, to prevent inflammation by partial starvation.' He asserts that he has witnessed practical benefit from this plan of treatment in many serious operations.

We are disappointed in the lecture on 'Excision of the Knee-joint.' The mode of operating is described, and the apparatus (Packard's) for fixing

the limb after operation, but guides with regard to the cases demanding exsection are wanting. The question of excision *versus* amputation is not discussed. He throws no light on the question of growth of the bone after exsection has been performed. Partial operations on the joint are advocated, but details of the signs and symptoms which indicate this mode of operating are not given.

The value of extension and the mode of making it are here as elsewhere in the lectures ably explained. However, we are not aware that Dr. Sayre's particular apparatus for making extension at the knee is more than exceptionally in use in this country. Trials of it were made after Dr. Sayre's visit and lectures in London in 1871, but the instruments did not come into general use. The principle of it is most admirable, viz., that of enabling the patient to go out and move about in fresh air, whilst the limb is fixed and extended. The same remarks apply to Dr. Sayre's splints for the treatment of hip-joint disease before and after operation. It is unnecessary to particularise them, for they are now no novelties to the public. Modern text-books on surgery describe them. His advice on the general treatment is sound and good, and that repeated under the head of disease of the hip-joint is especially good.

We looked for more details with regard to the cases in which exsection of the joint should be resorted to. 'If,' he says, 'we can satisfy ourselves that the articular surfaces have become ulcerated, the cartilages disintegrated, and the bones eroded, which is indicated by the presence of a crepitus peculiar to itself, we consider exsection of the joint not only justifiable but in most instances absolutely essential.' And, in another place, 'If, in spite of treatment, the discharge does not diminish but rather increases; if symptoms of progressive caries develop in the part, if the general health is daily becoming undermined, and there are no symptoms indicating repair, the only justifiable treatment left for the surgeon is exsection of the joint.'

In reviewing the history of excision of the head of the femur, Dr. Sayre claims to have been the first surgeon to operate successfully in America. We need not quote the description of the operation as now practised by the author. He preserves the periosteum and all the muscles attached to it. He removes head, neck, and trochanters. He claims for this method the advantages of free exit for discharges, reproduction of the bone, and free mobility. In describing the operation he lays down some useful rules, to one of which we would direct especial attention. It is to the effect that the surgeon is not to attempt to thrust the head of the bone through the wound to expose it for the application of the saw. 'If too free luxation is made you will displace the periosteum too extensively, and the consequence will be a subsequent enfoliation of the bone thus uncovered.' The after-treatment by the 'wire-breeches' is admirable. At the end of this lecture on hip-disease, he adds a table of fifty-nine cases (all his cases) of exsection of the hip-joint, and a synopsis. Of the total, twenty are dead. Of these fatal cases, eight had recovered from the operation some time previous to death. Eight only out of the twenty died from the exhausting effects of hip-disease, without some intercurrent complication.

Disease of the wrist-joint is only illustrated by one case. Disease of the elbow-joint is not discussed at all.

The chapter following the lectures on Hip-joint Disease is devoted to the diseases which simulate hip-disease. He would lead us to suppose that 'diastasis' of the head of the femur is frequently mistaken for hip-disease in America. In the twenty-fifth lecture we come to Diseases of the Spine. He confidently attributes Pott's disease to a traumatic origin and not to struma. The symptoms and mode of examining patients are graphically described. The apparatuses for diseases of the spine are very ingenious. We are struck by that for disease of the cervical vertebrae, and wonder whether it is practicable and can always be worn. The plaster of Paris cuirass in Pott's disease is economical, simple and useful; and the mode of keeping up traction on the spinal column whilst the plaster jacket is setting, is novel, to say the least of it.

The following lecture is on what Sayre designates Rotary-lateral Curvature. This form of deformity he attributes to abnormal muscular contraction, and he teaches that the inspiratory muscles are the agents in producing the primary dorsal curves. He condemns all fixed apparatus in the treatment, and declares the principle to be the stretching of those muscles which have been inactive and relaxed, and the approximation of the origin and insertion of those muscles which should remain quiescent. These ends may be accomplished, he says, in various ways. He employs, amongst other things, an apparatus consisting of elastic bands and leather pads. This contrivance might be called the Sayre-Barwell. The spiral corset is another suitable mechanism.

He narrates one case of deformity from contraction of the latissimus dorsi muscle, which he successfully treated by division of the fibres of the muscle near the angle of the scapula.

Remarks on Ankylosis follow. Our attention is at once arrested by a positive statement that therapeutic ankylosis should be straight rather than angular. He declares as his reason that the straight ankylosis 'gives a more secure position, and one that is not liable to give the patient trouble at some future date.' The angular ankylosis is in his estimation very insecure, and may accidentally yield. Fibrous angular ankylosis should not be treated by gradual slow extension, but by immediate restoration to the normal position by manual force, combined with tenotomy and myotomy if necessary. The rules for tenotomy are the same for this condition as for club foot. The *brisement forcé* is to be made thoroughly and not timidly.

He lays down rules for the after-treatment, and these are in accordance with his previously enunciated views.

Nine cases are detailed and illustrated. The drawings are, like too many others scattered through the volume, far from being as good as they might be.

The subject of bony ankylosis may be said to be limited to a study of this affection at the hip, knee, and elbow-joints. The hip-joint occupies twenty-three out of twenty-seven pages, and sixteen of these are devoted to one case, in which he had procured what he called an artificial hip-joint, by cutting out an elliptical segment of the femur, above the trochanter minor. In a former case he had obtained a similar result from a similar operation; but, as our notice of these lectures has already extended to a great length, we must refer the reader to the volume itself for further particulars. This is one of those important subjects which need additional illustration.

The work abounds in original and interesting matter; but we cannot refrain from expressing a hope that, if a second edition be called for, the author will exercise his great ingenuity and practical ability in condensing the text and improving the illustrations.

A Treatise on the Science and Practice of Midwifery.

By W. S. PLAYFAIR, M.D., F.R.C.P., Professor of Obstetric Medicine in King's College. In 2 vols. London: Smith, Elder, and Co. 1876.

Considering the importance of the subject and the absurdly short space of time allotted to its study during the student's curriculum, we are surprised that more works on midwifery than there] are have not been published. We welcome the present volumes as calculated to supply a want both to the student and practitioner, which has long been felt.

It is too much the custom for students to neglect the study of midwifery and diseases of women, thinking that they will soon be able to pick up a knowledge of these in actual practice, forgetful that this may thus be gained at the cost of much serious discomfort, danger, and loss to the patients.

Many contributions from authors well able to treat of the subject have been published within the last few years, such as Barnes's 'Lectures on Obstetric Operations,' Clay's 'Handbook of Obstetric Surgery,' Lloyd Roberts's 'Practice of Midwifery,' and others; but Leishman's 'System of Midwifery' has for some years past been the only really systematic treatise that has appeared, until Dr. Playfair presented us with the volumes before us, which, we venture to predict, will not only add to his own fame, but also prove of material advantage to students and practitioners, and be the means of saving many valuable lives.

The present treatise has been divided into two volumes, adding, it may be, something to the expense, but contributing materially to its portability: no mean thing in these days of ponderous tomes. The type is good, and is copiously illustrated by, for the most part, well executed plates, which facilitate much the explanation given in the text, though we trust in subsequent editions to see some improvement in these. Fig. 152, on page 183, gives but a very feeble idea of what should be the 'forceps in position;' they would inevitably snip off the head at the very first efforts at traction.

The plan of marginal notes is one to be commended. They facilitate reference, and serve to impress upon the mind the more important divisions of the subject.

It would be well in the next edition, to add an index to the first volume, as also to make the present index more copious.

The author has divided his subject into five parts: Anatomy and Physiology; Pregnancy; Labour; Obstetric Operations; and the Puerperal State. These again are subdivided into chapters. By this means, much needless repetition is avoided, and precision and accuracy encouraged.

The Anatomy and Physiology is ample, without being too diffuse, for a work of this nature. The illustrations are well selected and clearly drawn. The information conveyed is trustworthy, and, for the most part, up to date. Where any question is still *sub judice*, the author gives the opinion of others, and his reasons for inclining to one or other view, without entering too much into controversy. It would have been well had Williams's views on the

menstrual decidua been referred to, in place of the assertion that no exfoliation of the uterine mucous membrane ordinarily takes place.

The second part is devoted to Pregnancy in all its various phases. The chapters are replete with information, and include nearly everything that could possibly be expected, the subject being studied in its anatomical and physiological, pathological, and medico-legal relations.

The chapter treating of Superfoetation, Extra-uterine Foetation, and Missed Labour, will prove of interest to all. The varieties of extra-uterine pregnancy, and the mode of dealing with these, are given at length. The conclusions of the author vary, however, somewhat from those of Dr. Parry, more especially as regards aspirating the cyst in the early stages, which, as far as we have had an opportunity of judging, is attended by more risk than is supposed.

The Mechanism of Delivery, forming, as it does, the basis of all scientific assistance during parturition, is scarcely as clearly explained or illustrated as could have been desired. Fig. 88, on page 309, vol. i., by no means represents, as asserted, the attitude of the child in the first position; nor are the other illustrations as practical and explanatory of the text as they might be. We doubt the utility of attempting to describe the levelling or adjusting movement as the third stage; it complicates rather than simplifies matters; and, as this division of the subject is always a difficult one for the student to understand thoroughly, it cannot be made too simple.

The diagnosis of shoulder-presentations by external abdominal manipulation, together with the fact of being able comparatively easily to alter the position of the foetus, and thus avoid the necessity of resorting to the more serious form of version, is very properly strongly insisted upon, and cannot be too generally known.

The ordinary process of parturition should be a purely physiological one, and not, as too frequently happens, a pathological one. If the rising generation would only learn to appreciate how many of the so-called deplorable 'accidents' of labour might be avoided by a little forethought and methodical examination of patients, we should be enabled to diminish the mortality from childbirth to a very considerable extent. Not only does this apply to the maternal, but also to the foetal mortality. The timely application of forceps, where some disproportion between the size of the foetal head and the capacity of the pelvis exists, or where the expulsive pains are inadequate, determines the birth of a living child and lessens materially the risk of *post partum* hæmorrhage as well as that of septicæmia.

We are beginning now to understand the fallacious reasoning of those who, having collected statistics from every conceivable source, authentic or otherwise, tell us that the application of forceps is a dangerous innovation, and point to the mortality occurring in such cases; the truth being that so many mothers as well as children were lost because forceps were not applied earlier in the labour, instead of in consequence of their application.

The observations as to the influence of chloral in the early stage of labour, more especially in highly nervous and sensitive primiparae, we would commend to the attention of accoucheurs. Much unnecessary suffering may thus be prevented, and parturition also facilitated.

The employment of ergot very rarely indeed before

delivery, and the regular administration of a full dose after, as advised by the author, is one to be commended; hæmorrhage is thus frequently prevented, and the risk of after-pains and septicæmia also lessened. The plan of expulsion of the placenta by pressure over the fundus uteri, after waiting a reasonable time for the uterus to recover itself a little, is one that should invariably be followed in place of the method still pursued by many, viz., traction on the cord.

The chapter on Deformities of the Pelvis is eminently practical. His suggestion for estimating the amount of deformity and the relative merits of resorting to forceps; turning and the induction of premature labour or abortion are clearly stated. In fact, the work is one of great merit, and we have much pleasure in recommending it as a reliable and trustworthy treatise on a much-neglected yet highly important branch of medicine.

Commentary on the British Pharmacopœia. By W. G. SMITH, M.D. London: 1875.

If our notice of this volume be somewhat delayed, we have at least had a longer time to form a judgment about it; and having used it freely during a summer course of lectures on *Materia Medica*, we are enabled to speak with much certainty as to its merits.

Dr. Walter Smith, whose name has been well known for some time past, as the author of the 'Reports on *Materia Medica*,' and other papers, in the *Dublin Journal of Medical Science*, has given us a very well arranged and very accurate commentary, bearing more especially upon the chemistry and pharmacy of the *Pharmacopœia*. It is less technical and less experimental than Attfield's treatise; but its chemistry is very modern, set in an interesting manner, and is sufficiently complete. It is no doubt meant to hit the happy mean between what is desired by a scientific student, and by a practitioner who is willing to refresh his botany and chemistry with a definite practical aim.

Under the different substances, which are treated in alphabetical order, we find paragraphs on origin, preparation, characters and tests, adulterations, use in pharmacy, and a general description of medicinal use. Sometimes the dose is mentioned, and if it be not so always, this is in accordance with the principle laid down of not reprinting the text of the '*Pharmacopœia*.' We find concise and clear explanations of processes, and a free use of chemical formulæ, and many ingenious hints and notions as to reactions, and as to dispensing.

A good deal of care has been given also to tabular arrangements of different kinds; a substance, for instance, with many compounds, as mercury or iron, has them placed in 'genealogical tables,' according to their order of formation; and the official preparations are classed thus under mercury into 1, metallic; 2, oxides; 3, haloid salts; 4, oxy-salts; whilst mercuric and mercurous salts are explained and contrasted in parallel columns, and iron compounds similarly.

Again, the varieties of aloes, and the properties of creasote and carbolic acid, are well contrasted; whilst the constituents of opium, and the kinds of rhubarb, are other illustrations of the same idea. The list of opium-preparations is not complete; we miss the powder, the extract, and the suppositories with lead.

Some of the more difficult explanations of modern chemistry are required for the acids, the ethers, and

the alcohols; and in these we think Dr. Smith has been quite successful, but we prefer to choose for brief extract a few of the pharmaceutical points.

'*Acacia Gummi*.—The white precipitate with acetate of lead consists of gummate of lead (Pb_3O_5 , $3\text{C}_6\text{H}_{10}\text{O}_8$), and is characteristic of true gums; it serves also to distinguish the acetate from the sub-acetate of lead, as the former will not precipitate with pure mucilage.

'From the researches of M. Frémy, it appears that gum is essentially a combination of gummic or arabic acid with lime; or rather it is a mixture of the gummates of potassium, calcium, and magnesium. The iodine test will detect the addition of starch, but it is necessary to allow the hot solution to cool, as the blue colour of the iodide is permanently discharged at a boiling temperature.

'Gum is incompatible with alcohol or rectified spirit which precipitates it from its aqueous solution, and tinctura ferri perchloridi forms a jelly with mucilage, though not with dextrin.'

'The three monobasic organic acids, viz. acetic, benzoic, and carbolic, each give a characteristic reaction with ferric chloride; acetic acid, a blood-red solution, decomposed on boiling; benzoic, a bulky reddish-brown precipitate; and carbolic acid, with the *liquor*, a violet-blue colour.'

'The stratified appearance of white arsenic is due to its capacity of existing in both a transparent and an opaque state; when recently sublimed, it is vitreous, but when kept for some time becomes opaque, and as the change proceeds from the surface to the centre, a large mass is often found translucent internally.'

Under arsenic, we have an instance of an occasional defect which occurs in the construction of sentences, e.g.: 'The best signs of arsenic decidedly affecting the system are either gastric irritation and purging, or perhaps, *better still*, redness of the conjunctiva and lower eyelids, attended with itching, and possibly some oedema.' Such a sentence might be changed for the better in the next edition. And again, 'Pure hydrocyanic acid possesses *tremendous* energy.'

Phosphorus is a subject that would have borne more consideration, especially as to suitable forms for administration. We learn, however, that 'Fenian fire' was a solution of it in bisulphide of carbon, which information may serve to impress the knowledge of its best solvent. Phosphorus may be easily granulated by placing it in a stoppered bottle with proof spirit, immersing in warm water, and shaking till cold.

Under pepsin, the author remarks that many specimens sold are worthless, but does not give what we think an evident explanation—that *all* pepsines deteriorate by age; the mere keeping will spoil almost, if not quite all kinds, independently of adulterations. Liebreich's essence ought to be mentioned as amongst the best, and superior to any of the powders, unless they are very recently prepared.

There are many interesting derivations and etymologies interspersed; and, although we cannot quite agree with all of them, we must acknowledge room for two opinions on such points. For instance, we think *λῆδανον* a better derivation for laudanum than the old 'laude dignum.' But apart from minor criticisms, we may conclude with saying that Dr. Walter Smith has well put together a great deal of useful information in a very readable form, and that of his many facts and formulæ there is not one with which we are prepared to find fault.

Nice Médical; Climatologie, Médecine Pratique, Hygiène, No. 1. Nice, Octobre 10, 1876.

We welcome the appearance of this journal, and wish it every success. It proposes to accomplish a very important object, and if it succeed in doing so we shall be much obliged to its projectors.

Northern Europe and Great Britain send their thousands every winter to the south of Europe for the most varied affections, although pulmonary ones greatly predominate in number. Physicians until of late years have had a very imperfect notion of the climates to which they send their patients; and if they now know much more on this head than they used to do, still they have a very incomplete knowledge of the history of their patients after they have sent them to the south. Some physicians have indeed endeavoured to trace the progress of their patients' cases, but they can often learn little more of them than that they left them in a certain condition, and returned in a certain condition. We have no full histories of the action of these southern climates on the diseases of our patients. When physicians resident in one station do write monographs about them, their writings are rarely sufficiently discriminative. They are too much devoted to the laudation of their own stations, or of some particular favourite corners of their station. We seldom get clinical histories from resident physicians, and there is a sort of uniformity in the way in which every man tries to write up his own resort that is very wearisome, and that imparts no real information.

We hope that a journal like the one now projected will give us variety of opinions from different medical men, as collision of ideas helps greatly to elicit the truth; that it will not be confined to Nice and its immediate neighbourhood, but take a catholic view of southern health resorts. Even the little journal which has been carried on with much spirit at Dax—*Les Thermes de Dax*—if not one of much pretension, is useful in drawing attention to that corner of France, and in enabling us to compare the climate of the shores of the Mediterranean with that of the south-west of France, and in making the contrast of the two more marked.

The editor of the Nice journal informs us that at least 50,000 strangers visit Nice every winter, and that the field for observation is very ample; while the cases being less exclusively pulmonary ones than at some neighbouring stations, are more varied in their nature. The journal is intended to give an account of the proceedings of the Society of Climatology of Nice, which was established only a few months ago. Instead of the ten or twelve doctors of whom Nice boasted in Smollett's time, it has now nearly one hundred, so that the society should not want for members.

The present number contains an interesting article on the progressive increase in the number of births at Nice, showing at once the prosperity and healthiness of the place. It is to be continued in the next number.

Another article is devoted to the tonic and vivifying effects of the climate of Nice, and shows that it is particularly suited for childhood, and especially for old age; prolonging the latter, and making it more easy and agreeable. An account will be given of the various appliances in aid of the climate which Nice offers, and in this number some account is given of the Turkish baths. Full meteorological returns are to be furnished regularly.

But the articles are not all strictly devoted to Nice. There is one on the treatment of rheumatism with salicylic acid, and another on the pulse and temperature in cancer; also an instructive one on the abuse of injections of morphia.

If we would venture to give a hint to the editor respecting the portion of the journal devoted to climatology, we would say that perhaps the articles are inclined to run into generalities, while we should prefer seeing more details of individual cases. We hope also that the sanitary condition and drainage of Nice will not be overlooked.

NEW INVENTIONS.

THE PNEUMATIC INDIA-RUBBER VENTILATING COAT.

The medical profession have, as a body, unreservedly accepted the axiom that 'Prevention is better than cure.' The efforts of our most eminent physicians are now directed to the prevention of mental diseases by a healthy amount of mental and physical exercise, and to the prevention of bodily disease by attention to hygienic surroundings, pure air, pure water, wholesome food, and suitable clothing. Following in this sensible track, our manufacturers, never backward in taking a practical hint, hasten to apply the latest discoveries of science to the production of wares embodying the hygienic requisites appertaining to their special class of manufacture. In this moist climate of ours nothing is more indispensable to the medical practitioner, especially to the large class engaged in country practice, than a thoroughly waterproof coat. Many of us, doubtless, can recollect the ugly, malodorous, sticky garment which went under that appellation but a few years since. Not only, however, was the external appearance of the India-rubber coat unsightly in the extreme, but its very merit, the keeping out of wet, became a serious danger, since it also prevented all evaporation of the perspiration, which consequently became condensed on the skin, clogging up the pores, producing a chilly, clammy sensation, and frequently inducing rheumatic pains on the unfortunate wearer, who was thus placed between the Scylla of a good wetting and the Charybdis of a rheumatic attack. But in this, as in so many other matters of the hygiene of daily life, great improvements have been made. The ugly black sack has given place to a neat garment undistinguishable from the ordinary great-coat; and what is of really more serious import, ingenious appliances have been invented by busy brains to remedy the unhealthy effects of impermeable India-rubber outer garments. Of these, at once the newest and most effective has been brought under our notice by Messrs. C. W. Meiter and Co., of Gracechurch Street, who manufacture a variety of waterproof coats and cloaks. By the insertion of tubes in a loose lining, a space sufficient for the passage of air is created through the upper part of these garments; and the only other part where heat and moisture are engendered by wear, namely, the armpits, is ventilated by eyeletted tubes. By these simple contrivances all the inconveniences and unhealthy influences of ordinary India-rubber coats are completely obviated, and the wearer ensures to himself complete protection from wet, with perfect comfort and healthfulness.

THE PATENT POCKET INHALER.

This inhaler received the precursory title of 'Aleximorhygiastikon,' or 'the death-repelling, health-restoring, very simple and portable instrument,' but 'will be known hereafter' by the less ambitious title which heads this notice. We think, however, that the proprietors have done wisely in altering the name of the instrument to its present intelligible form. It consists of a small glass or metal tube, open at both ends, and containing in the centre some blotting-paper, for the reception of the medicated fluid, which at present is limited to carbolate of iodine. The proprietor claims for his inhaler the following advantages. 1. It is cheap, simple and efficient. 2. It admits the use of all volatile remedial fluids, in a concentrated form, without dilution. 3. It has a certain and unchanging area of exhaling surface. 4. It has a definite supply of air, which is in no danger of being varied. 5. It ensures nearly an equal rate of evaporation during inhalation. 6. It may be carried in the pocket and used at pleasure at all times and under all circumstances. The disadvantage of it consists in the fact that only those remedies can be used which are volatile at the ordinary temperature of the atmosphere. The proprietor of the 'patent pocket inhaler' is Mr. Austin, 7, High Street, Bloomsbury.

BRETT'S EAU-DE-VIE.

The only certain test for the purity of distilled spirits, namely, skilled chemical analysis, has been applied with very satisfactory results to Messrs. Brett's British manufactured Eau-de-Vie. We have now before us an analysis of this brandy made by Mr. Wanklyn, in which, amongst other technical details, with which we need not trouble our readers, he certifies that it contains 38.1 per cent. (by weight) of absolute alcohol, and that it is devoid of fusel oil. As a clean spirit of proper strength and purity, Brett's Eau-de-Vie may therefore be safely recommended to the profession and the public for medicinal and dietetic purposes. Much foreign brandy is sold, which is by no means free from the unwholesome constituents above named, nor from other well-known means of adulteration. As a substitute for these low-priced so-called Cognac brandies, Brett's Eau-de-Vie is valuable, since it fulfils all the purposes for which the administration of alcohol in that form is sometimes necessary, without the slightest danger of counteracting the beneficial influences of the stimulant by any unwholesome sophistications.

A NEW FOOD.

Semolina as a food for infants has not hitherto received the same amount of attention as arrowroot, tapioca, sago, and the various kinds of corn-flours. Yet from the large proportion of nitrogenous matter contained in it, it is specially adapted for the purpose and its peculiar richness in nitrogens has been skilfully utilised in a new preparation of semolina, manufactured by G. P. Bottasso, jun., Marseilles. The Semolina Bottasso has been submitted to searching chemical analysis by a well-known expert, Mr. Wigner, with the result of showing that it contains nearly 10 per cent. of flesh formers, which is taken by the manufacturers as a warrant that the semolina may be prepared without milk. Such a preparation for the reasons already mentioned might be more nutritious than the ordinary farinaceous infant's

foods, but to ensure both palatableness and nutritiveness the addition of a proportion of milk is desirable. As a light food for invalids and for the preparation of articles of food in the way of puddings, custards, etc., this semolina is both agreeable and nutritious.

ARTIFICIAL AERATED MINERAL WATERS.

Some samples of mineral waters and aerated drinks, manufactured by Mr. Hay, of Hull, have been submitted to us for trial. A careful examination has convinced us that they are very superior articles of their class. The potass, lithia, and soda-waters contain the proper amount of the mineral ingredient, are well aerated, and the water whence they are manufactured is pure. The lemonade and ginger beer are of a very superior quality and flavour to the drinks frequently sold under those names. Mr. Hay has bestowed much skill and care on their manufacture, and with very satisfactory results.

RECENT FRENCH BOOKS.

 Du traitement topique de l'endométrite à l'aide du graphidomètre, ou pinceau utérin, par le docteur Rénier (Saint-Augers), in-8. Prix : 50 c.
 Contribution à l'étude du tétanos, étiologie, température et traitement par le chloral, par le docteur Chopard, in-8. Prix : 2 fr. 50.
 Leçons sur les maladies du système nerveux, faites à la Salpêtrière, par le docteur J.-M. Charcot, recueillies par Bourneville. Tome 1er : Troubles trophiques; Paralyse agitante; Sclérose en plaques; Hystéro-épilepsie, etc. 2e édition. Vol. in-8 de 428 pages avec 27 figures dans le texte, 9 planches en chromolithographie et une eau-forte. Prix : 13 fr.

Published by J.-B. Baillière & Sons.

- Manuel pratique des maladies de l'enfance, par M. A. D'Espine, professeur de pathologie interne à l'université de Genève, et M. Picot, médecin du prieuré à Genève, in-8 de 599 pages. Prix : 6 fr.

MISCELLANY.

PROFESSOR MEYNERT of Vienna, a few days ago, accidentally slipped down the stairs of his house, and broke both bones of one leg near the ankle-joint.

NORTH LONDON MEDICAL SOCIETY.—The following officers have been appointed for the ensuing year: *President*, Thomas Stretch Dowse, M.D.; *Vice-President*, George Henty, M.D.; *Treasurer*, Robert Hilliard, M.D.; *Secretary*, W. H. Kesteven, M.R.C.S.

TRANSATLANTIC LIBERALITY.—It is said that the College of Physicians of Philadelphia has purchased the extensive collection of preparations illustrative of the anatomy and pathology of the organ of hearing, sent to the International Exhibition by Professor Politzer of Vienna.

DRUGGISTS IN FRANCE.—There exist in France 6,210 druggists' shops, of which 2,121 are of the first, and 4,089 of the second class. In 1866 the total number was only 5,803. Calculating the population of France, this gives one druggist to every 10,000 inhabitants.

A NEW APPLICATION OF SCIENCE.—Dr. Janssen is devising an automatic photographic revolver, which will take a photograph every hour from sunrise to sunset all the year round. Only those taken when the sky is free from clouds will be useful for recording sun-spots, but the rest will be used for meteorological purposes.

THE Manchester papers announce that Mrs. Crace Calvert has presented to Owens College the sum of 700*l.* for the foundation of a scholarship in chemistry, in memory of her late husband, Dr. Crace Calvert, F.R.S. The scholarship will be of the annual value of 25*l.*, and will be competed for by members of the evening classes.

To fill the vacancy in the chair of surgery in the University of Heidelberg, caused by the death of Professor Simon, an unanimous invitation on the part of the professors has been sent to Dr. Czerny, who has for some time filled the analogous chair in Freiburg. Dr. Czerny was formerly an able assistant of Professor Billroth of Vienna.

THE Medical and Surgical Society of Bordeaux offers a prize of 1,000 francs, to be awarded at the end of 1879, for an essay on 'The Microscopical Study of Human Blood, fresh and dry, in the foetus and in the adult, compared with that of other mammalia, in a medico-legal point of view.' The essays are to be written in French or in Latin, and sent to M. Donaud, Secretary of the society, before August 31, 1879.—The Medical Society of Toulouse offers two prizes of 300 francs each for essays on the following subjects. For 1877: 'The Mind in Disease; its physical, chemical, or microscopical characters; the analytical proceedings employed in order to detect these changes.' For 1878: 'What are the motives which, in late years, have led to the abandonment of blood-letting in the treatment of most diseases? Is the tendency to substitute tonics for antiphlogistics justified?'

MEDICAL STUDENTS, 1876.—The following is a list of the number of students of medicine registered at the Royal College of Surgeons of England this session from the metropolitan schools, distinguishing the new entries for the session. It will be seen that the number of new students is large, especially at the great city hospitals: 1. St. Bartholomew's, 374, including 131 new entries; 2. Guy's, 317, including 95 new entries; 3. University College, 279, including 79 new entries; 4. St. Thomas's, 177, including 43 new entries; 5. St. George's, 136, including 33 new entries; 6. London, 123, including 35 new entries; 7. King's College, 105, including 28 new entries; 8. Middlesex, 101, including 38 new entries; 9. St. Mary's, 82, including 26 new entries; 10. Charing Cross, 70, including 29 new entries; 11. Westminster, 28, including 9 new entries. The gross number registered amounts to 1,793, including 546 new entries, distributed in the follow-

ing numerical order: 1. St. Bartholomew's, 131; 2. Guy's, 95; 3. University College, 79; 4. St. Thomas's, 43; 5. Middlesex, 38; 6. London, 35; 7. St. George's, 33; 8. Charing Cross, 29; 9. King's College, 28; 10. St. Mary's, 26; 11. Westminster, 9. The above includes dental students.

M. LECLANCHÉ has just constructed a new galvanic battery, which the *Annales Industrielles* thinks likely to render great service both in manufactures and in scientific research. The original oxide of manganese battery by the same inventor consists of a porous jar filled with pyrolusite, in which is contained the carbon forming the positive pole. This jar is immersed in a solution of sal-ammoniac in contact with zinc. M. Leclanché has, however, introduced several improvements into this battery. He has superseded the porous jar by conglomerating the oxide of manganese, mixed in nearly equal parts with carbon, but with the addition of a small quantity—5 per cent.—of resin for the purpose of giving consistency to the mass. These three substances, properly pulverised and intimately mixed, are conglomerated under a considerable pressure, and at a temperature of about 100° Cent.—212° Fahr.—into a solid cylinder, which serves at the same time as a porous diaphragm and a positive electrode. But here a difficulty occurred. Under the influence of the current, an almost insoluble oxychlorate of zinc was formed, which was deposited in a crystalline form in the pores of the electrode, and considerably diminished its conductivity, so that the internal resistance of the battery increased very rapidly, occasioning considerable inconvenience, especially when used for telegraphic purposes. M. Leclanché has now got rid of the difficulty by inserting in the centre of the carbon and manganese electrode, while being moulded, a small cylinder of bisulphate of soda. This acid salt prevents the formation of the oxychlorate of zinc; and the battery preserves its regularity for more than a year without the necessity for renewing the water of the saline solution. It offers a much slighter resistance than other batteries, and gives out a considerable quantity of electricity. A single element of small size, presented by M. du Moncel to the Académie, immediately caused a platinum wire connecting its two poles to become red hot.

SPIRITUALISM AMONG THE MAORIS.—According to Lord Pembroke, in 'Old New Zealand,' the priests would, and do to this hour, undertake to call up the spirit of any dead person if paid for the same. A young chief had been killed in battle, and at the request of his nearest friends a priest had promised on a certain night to call up his spirit to speak to them, and answer certain questions they might put. The appointed time came, and at night we all met. Fires were lit, which gave an uncertain flickering light. The priest retired to the darkest corner. The door of the room was shut; the fire had burned down, leaving nothing but glowing charcoal. The light was little better than darkness, and the part of the room in which the priest sat was in perfect darkness. Suddenly, without the slightest warning, a voice came out of the darkness:—'Salutation! salutation! to you all. Salutation! salutation! to you my tribe-family, I salute you! friends, I salute you!' At last the brother spoke, 'How is it with you; is it well with you in that country?' The answer came (the voice all through, it should be remembered, was not the voice of the priest, but a strange melancholy sound like the sound of the wind blowing into a hollow vessel), 'It is well with me. My place is a good place.' The spirit spoke again, 'Give my large tame pig to the priest, and my double gun.' A 'test question' was then applied to the spirit which only deigned the reply, 'Farewell, O tribe! farewell, my family, I go.' Here a general and impressive cry of 'Farewell' arose from every one. 'Farewell,' again cried the spirit, from deep beneath the ground. 'Farewell,' again, from high in the air. 'Farewell,' once more, came moaning through the distant darkness of the night. 'Farewell.' I was for a moment stunned. The deception was perfect.

A MEDICAL ASSOCIATION IN NEW ZEALAND.—An endeavour is being made to combine the members of the profession in New Zealand into an Association having a similar organisation and objects to those of the British Medical Association. The promoter of the scheme is Mr. Millen Coughtrey, who was formerly attached to the Liverpool School of Medicine, and is now Professor of Anatomy in the University of Otago.

HORNED MEN IN AFRICA.—At the recent meeting of the British Association in Glasgow, Captain Cameron read a portion of a paper, written by Captain J. S. Hay, relating to a strange malformation in the males of a tribe of people he had visited in the district of Akem, in West Africa. The extract was as follows. 'Two diagrams which are laid before you depict to the best of my ability, and will at least convey some idea of, a malformation which is, I believe, peculiar to this tribe. I have at least noticed it in no other. My statement on this subject in an earlier paper, read before the Geographical Society in London last June, seemed to awaken considerable interest and astonishment (not unmingled, perhaps, with some incredulity), and attracted the notice and attention of such learned authorities as Professor Busk, Professor Huxley, and Mr. Francis Galton. With the last-named gentleman I had some correspondence on the matter, and I have endeavoured, in answer to the questions he then put to me, to amplify and elucidate a little further my original remarks on this curious point. The malformation in question is confined to the male sex, and consists in a protuberance or enlargement of the cheek-bones under the eyes, which take the form of horns on each side of the nose. This malformation begins in childhood, but is not, so far as I am aware, hereditary. It presents no appearance of being a diseased structure, nor is it a raised cicatrix after the fashion adopted by many African tribes. On the contrary, I have seen children with this peculiarity of structure whose parents were doing their utmost (though ineffectually) to stop it by medicines and applications. In the meantime to set all speculation and conjecture at rest, and to corroborate a statement that doubtless may appear extraordinary, I have lost no time in writing to a missionary, a native of the country, to procure me, if possible, skulls in which the phenomenon appears, and as soon as these arrive it is my intention to exhibit them in connection with a paper on the subject, which I propose to read at the Anthropological Institute in London.'

LUNACY IN SCOTLAND.—The eighteenth annual report of the Lunacy Commissioners for Scotland is issued. It shows that the total number of lunatics in Scotland, of whom the Commissioners had official cognisance, on January 1, 1875, was 8,225, of whom, 3,850 were males, and 4,375 females. Of these, 5,002 were in royal and district asylums, 226 in private asylums, 1,472 in private dwellings, and the remainder in parochial asylums and poorhouses, with the exception of 49 in the lunatic department of the Perth General Prison, and 143 in training schools; 6,700 of them are maintained by parochial rates, 49 by the State, and the remainder from private sources. Of the unreported insane, maintained by their friends in private dwellings, the Commissioners have no certain knowledge. The number of registered lunatics when the Commissioners first entered on their functions, namely, in January, 1858, was 5,823, so that there is shown in the seventeen years an increase in lunatics of 2,402; but this increase may in part be due to more lunatics in proportion to the total number having come under official cognisance. In 1858, the number of lunatics per 100,000 of population, was 191; in 1875, it was 230, there having been a gradual increase in the proportion during the intervening years. This proportion of lunatics to population is lowest in the country of Renfrew, where, in 1875, the figure was as low as 126 per 100,000; and highest in Kinross, with 375 lunatics per 100,000 of the population. The total number admitted to asylums during the year 1875 was 2,191, being 490 private, and 1,701 paupers. During the same period,

974 were discharged recovered; 397 removed, not recovered; and 561 died; the total number removed being thus, 1,932—of whom 461 were private, and 1,471 paupers. The average rate of recovery is highest in parochial asylums. This, the Commissioners say, is probably explained by the fact that the patients received into these institutions comprise a greater proportion of persons labouring under the ephemeral forms of insanity than those received into public and private asylums. Of the unrecovered patients removed, 21 escaped. The total number of escapes during the year was 257; of whom 161 were brought back within twenty-four hours, 60 within a week, and 15 after a week. There were six cases of suicide. The total expenditure for pauper lunatics in Scotland was, for the year ending May 14, 1875, 157,806*l.*, being nearly double the amount expended in 1858. The amount paid from imperial sources towards the support of these lunatics was 59,483*l.*, so that the direct burthen on the payers of parochial rates was 98,323*l.*

THE MILITARY HOSPITAL AT NISH.—The correspondent of the *Standard* thus describes this hospital. 'Although the hospital, like all oriental buildings, is especially built to gain as great a current of air as possible—windows and doors are always directly opposite each other—yet a pestilential atmosphere prevailed in the rooms, as the wounded are so crowded that sometimes a hundred were in one room where there was not really space for fifty. In general, the number of cuts and bayonet thrusts was small, that of the gunshot wounds very great; in some rooms a number of the men had been shot in the back. The wounded arrive from the battle fields in a pitiable condition, the balls and splinters of bone have not been extracted, their wounds are only closed with *ferrum sesquichloratum solutum*, and for days the balls sometimes remain in them, causing the most dreadful incrustations to be formed. The rational treatment of the patients meets with many difficulties, especially, as already stated, from the want of space, of good air, and a greater number of skilful doctors and nurses; then, in the absence of proper syringes, the doctors are obliged to use little glass ones, and the cleansing of the wounds being thus only imperfectly performed most of them assume a dangerous character, and the mortality increases in an alarming manner. The operations are performed by a professor of surgery, who came from Constantinople for this purpose accompanied by a number of medical students, but he brought such an imperfect supply of instruments with him that every operation occasioned a great loss of blood. At last a young Viennese surgeon, Dr. Lichtenstein, proposed that the so-called Esmarch's knife should be used, and, as no other instrument of this kind was to be found, he placed his own at the disposition of the operator. Since then the loss of blood during the operations, and the number of those who die from them, have been less. By the side of these dark shadows there is also the bright side in the hospital; the view from every window is lovely, and has a wholesome effect psychologically on the patients; the food and attendance, considering the circumstances and ordinary habits of the Turks, excellent, and never did a doctor find more patient and obedient patients than the wounded Turks. They never complain, always have a smile for the doctor, and thank him for dressing their wounds or other assistance. Even from the dying, whose wide-open, staring eyes proclaim their approaching end, not a sigh is to be heard, and often their faces assume a grateful expression, or they give some friendly sign when the doctor approaches. A case of wonderful stoicism also came under my notice. An Arnaut had his thigh amputated, an operation which might well make even a doctor shudder. The breast of the French surgeon, Larrey, who undertook such an operation on the battle-field of Wagram, must, so a Prussian doctor said to me in 1866, have been like that of the first mariner in Horace's ode, encased in *as triplex*. The Arnaut took no narcotic, and did not distort a muscle during the operation.'

ON FUNCTIONAL SPASMS. BY S. WEIR MITCHELL, M.D., MEMBER OF THE NATIONAL ACADEMY OF SCIENCES.*

I should scarcely have thought it worth while to recall attention to the obscure subject of functional spasms and its near clinical relatives, were it not that, in some of the most annoying and seemingly hopeless cases, I have been able to give so much relief as to enable the sufferer to resume his place among the active. Yet, besides this, some of the forms of spasm which I shall describe under this name, are not as yet fully recognised, or are seen so rarely in every-day practice, as to be looked upon as mere curiosities, or as utterly beyond therapeutic help.

Duchenne de Boulogne, in the second edition of his great work on Electro-therapeutics, has given the name of functional spasm to 'an affection characterised by pathological contractions, painful or not, but manifested only during the exercise of certain voluntary or instinctive movements.' He gives first the classical illustration of the various forms of writers' cramp, and others in which the biceps and deltoid contracted painfully when the hand was used. Then he refers to the spastic disorders of shoemakers, tailors, etc., and to the case of a fencing-master, who had contractions of various muscles when employing them in the habitual acts of his business. A large number of such examples might be cited from this author and from others.

Putting aside these well-known instances, I desire to call attention to a class of cases which, although nearly related to those just mentioned, differ from them in several most important particulars. They consist of three distinct classes: 1. Those in which the functional activity of a muscle or set of muscles gives rise at times to an exaggeration of the motions involved naturally, and sometimes also to more or less spasmodic activity in remoter groups; 2. Those in which the functional action of one group results only in sudden and possibly in prolonged spasmodic acts, tonic or clonic, in remote groups of muscles not implicated in the original movement; 3. Those in which standing or walking occasions general and disorderly motions, affecting the limbs, trunk, and face, and giving rise to a general and uncontrollable spasm without loss of consciousness.

The first group is, to my mind, one of the most curious. The pure instances, that is, those in which a normal motion is liable to become excessive, are rare. Some cases of writers' cramp nearly fulfil the conditions; but here pain or sense of fatigue is often, nay usually, superadded, and the overaction is not merely excess, but involves incoordination

almost inevitably. I mean, therefore, that there exists a set of rare cases in which the motor act becomes suddenly exaggerated. The result may be temporary, as in the following history of a man who came under my care some years ago. He was engaged in the manufacture of watches, and had in it some work which required him to be constantly picking up and adjusting tiny screws. When I saw him, he had been thirty years at this labour. His general health was faultless; but within two years he had acquired a strange peculiarity which made it impossible to do any steady work. When I began to question him as to this matter, he said 'Let me show you,' and asked leave to pour out some sugar-coated pills which were in a phial on my table. He then began to pick them up, which he did easily. Then he said, 'These are too large,' and at last took a wooden match and broke it into small bits, which he put on the table. As he picked these up he stopped at the third one, and said, 'There it is, locked at last.' I found that the forefinger and thumb were, as he truly said, locked on the morsel of wood. I forced them open with great difficulty, and was surprised to find the spasm stronger than his normal power in the same parts. This locking took place ten or twelve times a day, and was apt to last from ten to thirty minutes. He would succeed usually in pulling out the imprisoned screw with a loop of twine, but its release did not end the spasm, and very often the screw cut his fingers. Of late, the trouble began to show itself in turning the pages of a book, when at times the finger and thumb would close with violence, and the page be torn. He made the interesting observation that the spasm came soon if he put himself in his habitual attitude when at work, but that it was long delayed if he stood when at his labour.

This was the best case I recall of pure spasmodic increase of a normal act. It involved no pain, and only at times caused slight tremor, as extreme muscular exertion is apt to do in many persons. The moment the spasm was over he could at once pick up a screw and continue to work. This man had a varied experience in treatment, to mention which in detail would be to name almost every potent drug at our disposal. I used several means to lessen the sensitiveness of the skin of the affected fingers, thinking it possible that the beginning of mischief lay there. Afterwards, at his earnest desire, I used various electrical treatment, in which in such cases I have little faith. All alike failed, and the record was much like that of writers' cramp. Nothing but rest aided him, and he finally left the city to reside on a farm in the country.

As we all know, many trades are liable to cramp of the over-used muscles, as in the hammer palsy described by Duchenne. The calf cramp of the turner in wood or metal. These are usually brief and painful. But sometimes they are of the nature of what I may call, as it is a truthfully descriptive phrase, lock-spasm, a permanent or lasting painless spasm, of which this is a good example.

A sawyer, aged about forty, temperate and healthy, was seized at the end of a long hot day's work with a sudden spasm of the biceps. The saw, drawn back to prepare for the downward motion, was arrested. He ceased work and went home. His wife said he had a 'cold stroke,' his doctor that he had a heat stroke, but at all events the biceps only gave way during the sleep of the night which followed. After the spasm had returned many times,

* *American Journal of the Medical Sciences*, Oct. 1876.

he came to me one morning with an attack in full force. After the first they came back at long intervals, but these soon grew less; and when I saw him the spasms took place once a day, rarely twice, nor could their length be predicted. The arm I saw was locked in the extreme of a spasm so violent that no effort I could make relaxed it, although I made efforts which it seemed to me might endanger the bones. On a second visit I walked with the patient to a grocer's near by, and there got the man to bend over so as to bring the forearm horizontal. Then I attached a scale-pan to the wrist by a broad band, while he stood bent with his other hand on a chair-seat. Then I weighted the scale-pan until, after it had held eighty pounds for five minutes, the arm began to extend, and at last suddenly gave way. This spasm did not return on removal of the weight, but I got no permanent therapeutic use out of the suggestion this gave me. The enormous amount of force generated to sustain eighty pounds at the end of a lever as disadvantageously situated in regard to its fulcrum and to its active mover as the forearm is in relation to its joint and to the biceps, suggests some interesting reflections. Yet the power here wasted is slight as compared with that evolved to sustain the years of spasm in some cases of hysteria.

In the case I have briefly related, I think that good was done by the use of the induction-current; one pole was put on the outside of the biceps below and one on the belly above, and the strongest endurable current was passed through it for two hours once a day, and whenever the spasm took place. After a time I also used hypodermic injections of atropia into the belly of the muscle, a treatment for spasm much employed with my colleagues, Drs. Morehouse, Keen, and myself, in 1862, while in charge of the U. S. A. Hospital for Diseases and Injuries of the Nervous System.* The same means are still in frequent use at the Philadelphia Infirmary for Nervous Diseases. These two means were, I think, of value, because the spasms became by degrees less, and after several months ceased; a very unusual result of treatment, if it was a result, in these forms of spasm.

The third case of tonic spasm which I shall place beside those already given, must owe what details I can give to my remembrance, as the notes are mislaid.

The sufferer was an officer in rugged health when shot through the forearm and arm at the same moment, and just as he was drawing his sword. He felt a shock, but was more conscious of the fact that he could not release his sword-hilt from his grasp. At last he took hold of the fingers with his left hand, and opened them. This is a not rare incident of arm-wounds, and had, I think, no near relation to what followed. The wounds partially divided both the median and musculo-spiral nerves, and he endured many months of torment with causalgia (burning pain) in the palm. At last he got well, and at the close of the war came to me for the trouble I shall now describe. At times, when holding anything in the grip of the right hand, he would have a sharp pain where the median divides in the palm, and instantly the flexors would violently close the hand. The spasm would endure for two or ten minutes, and then relax. I have seen his palm cut by the violence

with which the nails were driven into it. The initial pain left as the spasm began, and the spasm was not of itself painful. He believed that it was caused by pressure on a tender spot in the palm, but I never could cause it by direct pressure. The median branchings in the palm were certainly tender, and I therefore desired him to use the treatment by repeated blisters, which in the war and since I have found valuable in many local nerve-troubles. He used at last twelve blisters on the palm, with the result of ending, I think, altogether his annoying malady. I heard of him as well a year later.

In this last case there must have been a sensitised nerve-region, from which the morbid impulse started. It was really a case of reflex influence, and was sometimes amusing in its consequences, because the victim never knew when the grasp would shut relentlessly on what the hand held.

These cases are, I suspect, excessively rare, as are also those in which a normal muscular act causes remote associated movements. The most familiar case is that of the lifting of a palsied arm during the act of yawning.* Histrionic spasm of the face also offers some odd illustrations, as in the case of Miss Inman, given by Marshall Hall. Here voluntary drawing down of the right angle of the mouth caused at once spastic closure of the right eye. This very curious case began with general tonic spasm of the right side of the face. He quotes from a French journal a still more notable case. It is too briefly described as a ball-wound of the left side of the face. The wound healed easily, but whenever afterwards the man used the jaws in any way, to speak, to laugh, to chew, instantly the sublabial muscles passed into a state of violent spasm, producing the most hideous grimaces. The normal action of one muscular group evolved the abnormal response of another.

One of my own cases was as interesting. It belonged to the class of hypercineses, in which the spasms lie chiefly in the range of the spinal accessory and first cervical nerves.

R. L., aged forty-five, a plumber, previously in good health, was hurt in January, 1862, by the fall of a cake of ice, which struck him on the back of the head and knocked him down. He suffered only from stiffness in the muscles at the back of the neck. This never quite left him, and within three months his head was slowly drawn more and more to the left. Then the convulsions appeared, and at brief intervals he had horrible spasms in the trapezius, sterno-cleido-mastoid, tracheloid, and spinatus muscles. Every minute, at least, the head was jerked backwards and twisted to left, the shoulders drawn up, and a storm of rapid but energetic spasms swept over the facial muscles.

He improved very much while taking gelsemium and bromides in full doses, so that at last the abnormal actions above described became really trifling. I believe they came back the year after, but in the interval he had a form of trouble which was painful to see. Whenever he began to chew food, the submental muscles would jerk his mouth open, and so hold it until at last he would push it shut with his hand, and chew a little more before the spasm returned. When ready to swallow, his face presented a picture of terror. He would suddenly muster courage and swallow the contents of his mouth at a

* 'Gunshot Wounds and other Injuries of Nerves,' 1864, Mitchell, Morehouse, and Keen, p. 154.

* This act must have curious influence. I saw last year a case of slight strychnic poisoning, in which the act of yawning suspended the spasms.

gasp. Then instantly the jaw flew open, the head was drawn back and down on the left shoulder, the face was convulsed, sweat broke from his forehead, and the attack was at an end. Sometimes, if he could bolt his food very quickly, he escaped the consequences. In this and the last case the muscles involved are really part of the muscular apparatus for chewing, speaking, etc., but have only a subsidiary part; still they belong, as to their activities, to nerves other than the facial, and are in this sense remote.

I have since seen many cases of this form of spasm, and in nearly all the acts of laughing, talking, but, above all, chewing, seem to provoke the return of spasms. In one case the convulsive movement drew the head back, and bowed the spine, and passed off by a spasm of the gastrocnemial groups, so as to jerk him into a squatting posture.

These are hypercineses, in which the spasms, usually active with or without apparent cause, are also brought on or increased by the functional activity of other muscle groups, allied or remote.

I have seen also certain spasmodic cases in which all of the abnormal phenomena were related to the physiological act of walking—I might define them as being exaggerations of walking. I have seen this disorder in various forms.

My first case was a chubby, ruddy little boy, aged six, from Tennessee. I could find neither in his own nor his parents' history any cause for his disease, save that it came on slowly after measles. When asked to walk, he exhibited this strange set of symptoms. The left leg was sound and acted well. As he swung the right forward, and lifted the toes to avoid touching the ground, there was first a sudden spasm of the tibial and peroneal muscles, so that the tip of the foot was jerked up too high. Instantly it seemed to relax, and the foot came down, but, as it touched the ground, and the second physiological act of rising on the ball of the foot began, this became extreme and spasmodic. The lad was lifted abruptly, and, the spasm of the gastrocnemii continuing, the leg was jerked up backwards—a true string-halt. I had never seen this before, and was much interested. While at rest on his back he moved the foot at will without annoyance or spasm, nor could I by a blow, or pressure, or tickling of the sole, cause him to repeat the movement.

In July, 1875, I saw at my clinic a case somewhat like the last, but with some important differences, in a delicate looking girl, aged seven, with a good family history, and no cause to which I can trace her troubles of locomotion. She began to crawl at two years, and never walked till the fifth year, yet with this slowness to move there seemed to be no arrest of mental or moral development. The mother thought that she was gaining ground. When we stripped her, I found that she had all the foot-motions perfectly, save that of flexing the feet, which, when they got to a right angle with the leg, could move no further, the tendo Achillis refusing to yield. The other muscles above the knee were in that curious state which we find in some partial palsies in adults, and which Dr. Seguin has admirably described. It is a condition of rigidity which varies in degree in different cases. In this state, if you flex the leg on the thigh, the extensors, which should be passive, slowly, and, as it were, reluctantly, act and resist the flexion. If you extend the leg, the flexors act to resist in like fashion. Whatever motion be made, the opponent muscles contract, and every willed

movement becomes tardy and difficult, or, in bad cases, impossible. When an attempt is made at passive motion, the muscles do not resist in jerks, but smoothly and evenly, so that it seems as if you were bending a stiff hinge or a bar of soft metal. In fact, so striking is this analogy, that at my clinic this state has come to be briefly described as the 'lead-pipe leg.' In the present case it was not extreme in degree. Voluntary movement in walking curiously exaggerated the gastrocnemial spasm. Every time the foot came down the gastrocnemius muscles contracted violently, and so as to lift the child with a jerk on to the foot then in use. If the walk were rapid, she walked continuously in this position. If she moved slowly, the gastrocnemius only acted as she rose on the ball of the foot, the natural physiological act becoming excessive.

Here was then a slight but permanent tonic spasm of the calf-muscles, yielding easily under ether, with a temporary functional spasm alternating in each leg as she used it in walking. After some reflection, Dr. T. G. Morton cut the tendons of the calf-muscles on both feet; and, as a result, the muscles, in place of continuing to contract, relaxed, as the resistance ceased. The tendons were thus lengthened at least two inches, but ample power remained, and the walk was most satisfactorily improved.

The next case is yet more curious.

R.C., aged seventeen, a long, thin, sallow lad, from New Jersey, was brought to me in October, 1874. Healthy up to the age of nine, he had then measles, from which he recovered very slowly, and with marked feebleness of the legs. As time went on, the power to use them increased, but by degrees there came upon him a certain stiffness, which extremely embarrassed him in all his movements. At the time I saw him his legs were equally developed, except that just above the left knee the thigh-muscles were somewhat wasted. While in bed at rest the legs were quiet. When he stood up the spinal erectors became extremely rigid, and threw the back into a bow, while a strong effort of will was needed to keep the left leg quiet, and sometimes, the effort being insufficient, it was jerked upwards. When seated, he kept the leg still by crossing over it the more manageable right leg. When he walked, each leg in turn was jerked up by the gastrocnemii, so as to constitute a string-halt, which, as he was swayed to right or left, and bent back by the alternating activity of the spinal erectors, caused him to present a most curious appearance. For instance, on coming to a stand after rapid walking, the spine was bent forward, the belly thrust out, the legs bent, and the lad balancing on the ball of the right foot, with the left leg jerked up at a right angle.

At first I felt indisposed to attempt any treatment of this puzzling case. Various electrical treatment was tried and failed, such as induction currents to the antagonist muscles, or long-continued induction currents to weary the spasmodically acting muscles, and Remak's rapid alternatives.

A long series of atropia injections into the calf-muscles met with more success, and the action of these muscles became distinctly less powerful and less troublesome. Next I weakened the back muscles by a series of repeated cross sections at different levels; and finally I put on him an apparatus which limited the extent to which the over-active muscles could move the various parts of the limbs. I did not cure him, but I most certainly did remark-

ably better his condition, and enabled him to rise, stand, and walk with far less fatigue and effort.

The last two of the cases I have here given involve spasm or increased spasm in groups of muscles accustomed to act together in order to secure equilibrium when standing, or to aid in the movements of progression. The cases first given were also examples of voluntary action bringing on or increasing spasm elsewhere, but, save in the case of yawning, and the consentaneous arm-lifting which it causes in some hemiplegias, the muscles which contracted convulsively were not remote from those whose activity seemed to call them into morbid motion. But in the case which I shall now present, the most prominent feature was the fact that every or almost every voluntary motion caused extraordinary changes of or increase in the amount of the spasm, and this was the case whether the patient was prone or erect.

R.C., aged thirty-three, watch-case maker, married, had healthy children; no syphilis. His family history was bad; a sister, two aunts, and his mother had palsies in middle life; an uncle had epilepsy, and a cousin dementia. He was always nervous and excitable, used no spirits, smoked moderately, and was always well until the summer of 1865, when he was two days unconscious from sunstroke, and had ever since been made weak by the heat of summer. About two years ago, in the summer of 1874, he observed that while walking the legs felt weak, and he was obliged to stop, as if to regain power; after which the right leg would drag for a time. At the same time he began to have pain in the back of the neck and lumbar spine. These pains continued. In January, 1875, he noticed a slight but increasing tremour in the left arm, and in two or three months the strange condition which I shall try to describe.

When I first saw Mr. C. he was a healthy-looking man, of unusual intelligence, and marvellously patient under his great suffering. In sleep there was no movement; when he awoke, he was conscious of the left hand being rigidly closed. In a few moments it began to twitch, the fingers moving as do those of a violin-player. The slightest movement of any other limb, speaking, or eating—even if he were fed—caused the left arm to execute a constant motion of striking the bed or his side, the limb being the while extended. When he arose and walked, this action became more violent, and so much resembled the steady, rapid movement of a pendulum, that I spoke of it at once to my assistants as a case of what might be called, descriptively, *pendulum-spasms*. In fact, its rhythmic regularity was astonishing. Dr. Sinkler timed it, on one occasion, as 157; and on several others I found it always exactly 160. It was as accurate as the heart in its motion, but certain things always increased either the power or the number of the motions. Thus if he stood up, having been seated, the number did not alter, but the force of the blow on the thigh increased remarkably.

If, while standing, he elevated and extended the right hand and arm to the shoulder-level, instantly the rhythm mounted to 200; and when the right arm ceased to act, the number fell again speedily to 160.

When there was no pendulum-spasm, he could perform with the left arm any voluntary act not involving the hand, which itself never ceased to twitch; but while the swinging spasms lasted he

could execute no volitional act, and the effort to move the limb enormously increased the spasms.

Excitement and emotion, and all forms of electricity, added to the force of the motions, but voluntary movements of other limbs increased the number more than the force. Attempts at passive motion, as the effort to fully extend the partially flexed fingers, caused intense pain in the occiput, just as the effort to overcome rigid gastrocnemii in certain cases gives rise to pain in the dorsal spine. He had power to stop the spasms by certain manœuvres. If he seized the left hand with the right, and, flexing the left arm, held it, there was a kind of general spasm; the left hand for a moment seemed to struggle with increasing violence; he tottered; the face was convulsed; there was horrible pain in the back of the head. Then he gently released the left arm, which, save for a slight tremor or twitching of the unquiet fingers, remained at rest, and might not move in violent spasm for an hour or more, and was sometimes nearly still for twelve hours.

He avoided the use of one hand to stop the other, because of the great pain it caused in the head. When he stopped the hand with his leg, he had little head-pain, but it was altogether so unpleasant for him to check it that he rarely did so. When standing, if he wished to stop the pendulum-spasm, he threw the left leg back so as to trip the toe; the arm then fell in as it moved, and he brought the leg forward so as to catch the arm against the thigh, where its own spasm held it. Then there was a general convulsive moment of the entire body, and the limb was at rest.

When the arm was hanging quiet at his side, it began to move if he walked a few steps, or if he lifted the right arm, in which at times—especially after sudden arrest of the spasm—I noticed some large tremor.

In all of this strange set of symptoms there was no loss of consciousness, no anæsthesia, no ocular trouble or spasm, no aural defect. When he walked long or fast, the legs had some disposition to become rigid; but this was an inconstant feature.

There are several points of great interest about this notable case. No other is so good an illustration of the product of clonic spasm through remote voluntary activity. Also the mode of arrest is curious, and I should have added, in describing it, that a bystander can stop the spasms by securely holding the arm for a few moments, when the usual general contortions occur, and the limb ceases to move. Voluntary motions of remote parts—of any remote parts—set the spasms going. Forcible arrest of the spasmodic swing of the arm seems to cause a discharge of nerve-force from numerous nerve-centres, and so gives rise to a momentary generalised spasm. This last fact finds analogies in some spinal sclerosis, and in some clonic local spasms, the arrest of which occasions remote or morbid activities.

I saw, in the war, a soldier who had a constant *see-saw spasm* of the left foot, caused by a nerve wound of the sciatic. The flexors and extensors acted by turns, so as to keep the foot in constant motion. When I held it firmly, he was seized at once with a general left-lateral convulsion, in which the face moved but slightly, without ocular spasm or loss of consciousness, but with occipital pain. As soon as the foot was released, the other motions ceased. Sensibility was impaired from the peripheral lesion.

In the case of Col. P., described at p. 364 of my

book on 'Nerve-Injuries,' there was a continual irregular thrashing motion of an arm-stump, which ceased for a time, when the stump was exercised in voluntary movement, but which extended over a large region of the same side (right) with sense of discomfort in the head if an attempt were made to hold the agitated stump. These peculiarities seem to me worthy of note in cases so obscure, and the history of which has been thus far imperfect, because we are without *post mortem* results or interpretations.

There is yet another group of cases, happily most rare, in which, while the patient is at rest prone, or as in one case seated, no spasms exist; but when the upright posture is assumed, at once the patient is seized with general convulsive motions, which may or may not persist. Of such a disorder I have seen three cases.

The first and most singular was that of a journeyman tailor, about twenty-eight years old, a man of lean make, and very anæmic. He had been guilty of no excesses, and had not had syphilis. His secretions were normal, and his organs, to appearance, healthy. He had, however, worked hard in the cross-legged position which tailors assume, and had been constantly sewing late into the night. This was all that could be learned of his history.

When this man was seated or on his back, he could make every possible movement, slowly or as abruptly as he pleased. If he got up from his bed or a chair slowly and watchfully, and then stood still a moment, he could walk away as well as any one; but if he jumped up suddenly from the prone or the sitting posture, he was seized as by a spell with a convulsive attack, in which his head became giddy, but in which there did not seem to be the least loss of consciousness. As he made a sudden attempt to get up hastily, the right leg bent at the knee, the left was thrown over it, and grasped it in violent flexion. The body was twisted to the right, and the head also, while the right arm in extension was raised, and the left thrown outwards and backwards in extreme pronation. Then there was a general writhing of the whole frame, the face muscles twitching here and there, and with a groan of relief his attack was over.

Much pains were spent to learn if there was in this case any chance of explanation which would involve a suspicion of simulation. His malady, however, was very constant in its peculiarities. It had come on gradually, beginning with slight contortions; it made him unpopular in the work-room, where it was looked upon as some kind of possession; nor had he anything to gain by malingering, while his face had always that look of gloom and melancholy which such a torment as his would be apt to inflict on a person of sensitive temperament.

Dr. C. Handfield Jones* briefly calls attention to cases in which spasms occur owing to the weight of the body being brought upon the feet.

He mentions that Bamberger relates the case of a youth aged nineteen, convalescent from pneumonia, who had spasms of the legs when he touched the ground with his feet. There was tetanic rigidity, interrupted by violent sudden contractions, which increased in intensity. He says, also, that the face was flushed and distorted, but that all movements ceased when the lad lay down. If, while lying, the soles of his feet were pressed, the same phenomena appeared,

but with less intensity. He was cured by sedatives and cold affusion.

Bamberger's case is somewhat like the following, which I saw two years ago.

A lad, aged seven, of rosy tint and well nourished, had, when a year old, a sudden convulsion, and, soon after, a succession of fits, followed by several days of unconsciousness. His previous health was good; his family record was unimpeachable. When three years old he began to creep, but showed no desire to stand or walk. Long and strenuous efforts were made to induce him to stand, but he always drew his legs up and sank down. For a long while this was regarded as due to feebleness. By and by, however, despite the motions just mentioned, he would maintain himself erect, or partly so, and by the aid, for the most part, of his vigorously developed arms.

When I saw him I was struck with the child's intelligence, with his general look of health, and with the perfect use he had of all his members while lying down. Neither when he crawled could I see any failure of power or co-ordinating capacity in the legs.

After I had gone over his case with care, his parents placed him on his feet. I find it impossible to describe the confusion of motions which at once ensued: They seemed to me made up of choreoid movements of the hands, feet and face, with pretty violent alternate spasms of the flexors and extensors of the legs and arms, with strange rotatory twistings of the spine and neck. His face looked anxious, but twitched very little. When he was put on his back, every motion ceased at once. Pressure on the soles did not cause spasm. When held up by the arms or by the shoulders he had no spasms, but as soon as the feet were on the floor and he tried to stand, the storm of convulsive motions swept over him. The effort of standing seemed to be needed to cause the result. If he tried to walk he was thrown down by the spasms, and therefore did nothing but creep.

Electricity did not cause in him any spasms. The leg-muscles responded well to a moderate induction-current. There was no disturbance of sensation anywhere. When his soles were tickled he drew them up a little jerkily, but with no spasm.

I regret that this interesting case was seen by me but twice, and that my notes of it are not more ample. His parents, when once they learned that I did not regard the case as hopeful, were indisposed to give much information about it, and seemed to fear that the poor little fellow would be looked upon as a medical curiosity.

I believe I shall have done a good service by directing attention to the fact that voluntary motion may give rise to various forms of spasm. It is familiar enough that morbid sensations may do so, or that in an over-excited state of motor centres, a normal sensation may occasion like results, as in tetanus. As regards the cases to which I have here called attention, two explanations lie open to us. Voluntary acts give rise to spasms in the muscle willed to move, or in remote groups of muscles. There is at times an unusual discharge of nerve-force in some of these cases, as in the 'lock spasms' I have reported, or else the muscle itself has become the means by its over-use of hypersensitising the sensory centre which takes record of its activities, so that from this centre at times excito-motor impressions are radiated on to near or remote centres, and result thus in spasms. It will be found, in all of these

* 'Functional Nervous Disorders,' p. 398.

cases, that when an ordinary functional motor act gives rise to spasms elsewhere, these occur in muscles which have physiological and therefore anatomical relations to the muscles which, by their normal use, gave rise to the morbid activities. Thus, the face muscles are physiologically allied, and so volitional movements of one of them may cause spasms in others. The motion of one arm starts spasms in the other; and walking, which involves naturally the swinging of the arms, has a like potency. Why talking or chewing should do the same is less clear, but such morbid relationships have analogues in the cases of neuralgia, where the long irritation of one centre results at last in the like disturbance of remoter sensory centres and in radiated neuralgiæ, which are usually of unilateral relationship.

CLEEMAN ON METEOROLOGY AND EPIDEMICS.

The ninth volume of the *Transactions of the Philadelphia College of Physicians* contains a paper by Dr. Richard A. Cleeman on this subject, of considerable interest to those who study epidemics and

comparative meteorology. One fault runs through this, which is common to almost all similar reports. It is that the facts are not arranged in such a manner as to render them amenable to the criticism and comparison of practical busy men. There can be little doubt, in thoughtful and reflective minds, that Mr. Spencer Wells is quite right in his opinion, shared by some of the most successful operators on the continent, that the condition of the atmosphere in general has much to do with the success of operations. All who have long resided within the walls of a great hospital must know that a large majority of the deaths correspond with periods of great electric and barometric disturbances. But busy men cannot spare time to make elaborate tables out of papers like the present. Their compilers ought to present us with a *résumé* of the principal facts both of the weather and of the cases of sickness and mortality, so arranged that their parallelism or contrast is at once visible to the eye. We made the attempt to assist our readers in this matter as regards the paper before us. Unfortunately, however, such practical uses seem to have been but little contemplated by its compiler, and success has therefore only been partial:

General Characteristics of the Year 1875, in Philadelphia, United States.

Temperature	Barometer	Rainfall	Humidity	Winds	Prevalent Epidemics and Deaths.
The year was a cold one. The average temperature of the year was 50°·3° F., or 2°·7° less than average of 51 years. Lowest point, 5° F., January. Highest, 95° F., June, or an annual range of 100° F. The greatest range was in Dec. and Feb.; least in Aug. and July. The first frost was on Oct. 9.	Mean, 30°·059 inches, or the same as the average of last four years. The highest 30°·787 inches in Jan.; the lowest 29°·361 inches in Oct. The range for the year, 1°·426 inches. The greatest monthly range was during Dec., 1°·324 inches.	40°·24 inches of rain and melted snow, which fell in 154 days. (More rainy days, but less water than 1874, which had 46°·31 inches. In 1875, April showed only 2°·85 inches. The most rain in 1875 was in Aug. (6°·42 inches) and Nov. (5°·40 inches). An inch of rain is nearly 100 tons per acre.	67° (saturation being 100°) was the mean for 1875. (65° mean for 1874 though its rainfall was greater.) In August and Dec. 76°. (The highest mean.) Lowest point was in May (54°). The same thing was noted in May 1874 (58° mean for that year).	The prevailing winds were W. and S.W. The same remark applies to the year 1874. During March the prevailing winds were from the E., but this wind was not prevalent in any other month.	Out of 18,085 deaths (51°·21 per cent. males, 48°·79 per cent. females), in a population estimated at 800,000, Philadelphia, or 22°·6 deaths to the 1,000 living, 4,590 are put down to zymotic diseases. There were 56 from small-pox (21 in Dec.); 1,032 from scarlatina, Jan., Feb., March = 102, 89, 149; April, May, June = 121, 104, 171; July, Aug., Sept. = 87, 63, 30; Oct., Nov., Dec. = 33, 32, 31. Diphtheria, 656, (97 in Dec.). Croup, 429; Typhoid fever, 400 (less by 68 than 1874). Dec. and Aug. had most deaths from cholera infection, 992 deaths, mostly in June. Whooping cough, 125, nearly 1/2 in 24th Ward, or West Philadelphia, whose population is only 1/4 of that of the entire city. There were 20 deaths recorded from sun-stroke.

Dr. Cleeman calls attention to the simultaneous prevalence of scarlatina, croup, and diphtheria, and infers from local circumstances that some, at least, who made these returns, used these names one for the other. In view of recent discussions, this is an interesting observation. Another point of interest, also needing local knowledge to establish it agrees with general experience elsewhere, and that is that the diseases of the zymotic class, and especially deaths from this cause, depend chiefly upon conditions of imperfect sanitary arrangements. Most of these might and ought to be prevented. These epidemics may be, and doubtless are, like all mundane affairs, dispensations of Providence, but they will soon cease to be mysterious, and would most of them cease to exist, if we would only obey and enforce the divine laws of health. W. BATHURST WOODMAN.

LADREIT DE LACHARRIÈRE ON AURAL POLYPI.

In the *Archives des Maladies de l'Oreille et du Larynx* for August, 1876, Dr. Ladreit de Lacharrière

has a paper entitled 'Practical Considerations on Polypi of the Ear.' According to the author, polypi of the ear are of such common occurrence, that scarcely a week passes in which aural surgeons do not see them. In spite of this, however, a glance at what has been written upon them will suffice to show that the study of their growth is not yet complete. Toynbee classes three varieties, the raspberry polypus, the fibro-gelatinous polypus, and the celluloglandular polypus. Bonneton shows the analogy existing between aural and nasal polypi, and observes that the difference of structure which they present depends on the differing condition of the structures from which they originate. The most exact classification from an anatomical point of view is that of Roosa and Steudener, by whom they are divided into mucous and fibrous polypi, and myxomata. In the present paper, polypi are studied with especial reference to their state of origin and their treatment. Under the term polypi, however, must not be confounded malignant tumours of the ear, which are true cancers, develop themselves with prodigious activity, and have a great tendency to return after removal.

Bonnefont says, 'The point of insertion of polypi may be in all parts of the meatus and of the membrana tympani; but, contrary to the opinion of most surgeons who maintain that polypi rarely arise from the fundus of the meatus, I hold that one finds them more often near or on the membrana tympani than at the orifice of the meatus.'

Von Trötsch says that polypi may arise in different parts, the meatus being the rarest point of origin. Toynbee and Wilde, on the contrary, have most often found them in the meatus, the latter principally on its superior wall.

The experience of the author induces him to agree with Von Trötsch in considering polypi of the middle ear as much the most frequent, an attentive examination showing that in eight out of ten cases the cavity of the tympanum is the point of origin. Polypi developed in the cavity of the tympanum are generally of fibrous or fibro-cellular kind. They rarely contain spaces in their interior. In appearance they are whitish or slightly rosy, and somewhat dense in structure. They may originate from the walls of the meatus or the membrana tympani, but this is rare, the mucous polypi being those most frequently observed in the latter situation. These are whitish and almost transparent, containing spaces, or a cellular tissue, with rather large meshes, filled with a colourless mucous liquid. Their base is often very narrow; they are slightly adherent, and are easily, sometimes even spontaneously, detached. They almost always arise from the surface, but very rarely from the centre, of the membrana tympani; some point in the circumference being their most frequent seat. Von Trötsch observed a polypus due to a transformation of the membrane, all the elements of that tissue being represented in it.

On the walls of the meatus all the three varieties of polypus described by authors may be found, but more rarely than in the tympanic cavity. Their diverse structure may be understood from the various elements in which they originate. The mucous polypus originates from the glandular follicles, the fibrous from the inflamed periosteum, the myxoma or raspberry polypus from the surface of the bone itself, denuded either by ulceration or by circumscribed abscess.

Dr. Motte has made some researches on the causes of these morbid growths, the generally accepted theories of the production of tumours not satisfying him. He believes that the development and reproduction of aural polypi is always due to a sanguineous hyperæmia, or to a plastic exudation. 'Let us destroy,' says he, 'in any manner, a polypus which has existed many years, at the fundus of the meatus; if it is rather small, and its pedicle narrow, this pedicle will give passage to one or more vessels relatively of considerable size, the obliteration of which will only throw the trouble on to the neighbouring parts, nourished by the collateral branches in connection with it. Von Trötsch has shown that the external auditory meatus and the membrana tympani receive their vessels from the same vascular trunk, viz., the deep auricular artery. It follows then that the membrana tympani in particular becomes the seat of a hyperæmia, which will furnish the elements necessary for a series of remarkable organic evolutions.'

With this theory, however, the author does not agree, but believes that inflammation will account for all the morbid productions of the auditory meatus, and explain their recurrence and multipli-

cation. Here, however, we may ask, is not hyperæmia the first primordial element in inflammation? Yes, but it is only the initial element. Sometimes, in fact, it is as the sequel of otorrhœa which has lasted a long time that we see a polypus appear. The cause here is evident, and it is the most common. If the affected surface be cleaned, ulceration is seen on which growths originate just as in all wounds, and these growths develop polypi. At other times, on the contrary, the polypus seems to be the cause of the otorrhœa, and this is proved by the fact that its removal is followed by immediate cure.

If we then seek for the point of its implantation, we find it very limited, and are led to believe that an inflamed glandular follicle or a little abscess has been the origin of the tumour. In either case, inflammation is a sufficient cause for the malady.

What has been said as to the nature of aural polypi shows how useful it is to look for the points of growth before determining what means shall be used to destroy them. These proceedings will differ according as the polypus has its seat in the auditory meatus, on the membrana tympani, or in the tympanic cavity. The nature of the tumour will also influence our choice of procedure.

The introduction of a stylet will tell us whether the polypus arises from the wall of the meatus. Its penetration very deep will show that the growth comes from the tympanic cavity. This mode of exploration, however, will be incomplete if the polypus, developed in the tympanum, emerge through a small perforation in the membrane. We must remember, however, that fibrous polypi most commonly arise from the cavity and rarely from the membrane. A mucous polypus, on the contrary, may be presumed to arise from the membrane. In cases of doubt a loop of wire carried round the tumour by a stylet will close up the diagnosis. It will now be necessary, as Bonnefont recommends, to examine the state of the function. If the watch or the tuning-fork be heard most clearly on the mastoid process, the chances will be considerable that the obstacle is not in the tympanum, and that the polypus originates in the meatus. If, on the contrary, the watch be heard equally badly everywhere, the situation of the polypus will be the opposite.

Now, as to the treatment of aural polypi; the three methods which have been employed are evulsion, excision, and cauterisation. Evulsion is an easy method, and consists merely in seizing the polypus with forceps and twisting it on itself until it is detached. This method, which is without danger for polypi of the meatus or for mucous polypi of the membrane, which are detached with the very slightest force, will not be without inconveniences in cases where the polypus arising from the membrane is fibrous in character.

We shall be liable to tear the membrane and dislocate the handle of the malleus, or to produce more or less serious lesions in the cavity and strippings of the mucous membrane, the consequence of which it would be difficult to foresee; finally, hæmorrhage might be produced to a serious amount. Wherever, therefore, any doubt exists as to the seat or anatomical structure of a polypus, evulsion must be renounced, and excision employed. This operation may be performed by scissors, thin and curved on the flat, but for their use the meatus must be somewhat large, and the polypus small. With scissors,

also, we are liable to cut above the pedicle, and this will always happen with polypi of the cavity. A metallic wire is preferable; Wilde's polytome being the instrument most often employed. Some recent modifications by Dr. Desarmes and the author have made this instrument more convenient. With it excision of the polypus is easy, and the patient is not exposed to any of the dangers of evulsion. In order to use it with certainty, the point of implantation of the tumour must be found. If the tumour be not cut at its base and reproduction seem probable, the morbid growth must be treated by cauterisation.

The caustic most frequently employed is nitrate of silver. Although it is the most innocent it is also the most unreliable. The cauterisation being very superficial, it sometimes, instead of destroying the disease, sets up a new morbid action for its reproduction. Von Trötsch recommends Vienna paste and chloride of zinc. The Vienna paste, from the facility with which it flows, affects parts which we wish to preserve. Acid nitrate of mercury and chromic acid destroy the tissues deeply, but they destroy more deeply than we wish, and expose the patient to serious inflammations, and sometimes also cause severe pain. The author has sought a caustic the action of which should not be too violent, but should be capable of destroying what he wished to attack. A remembrance of Dr. Maisonneuve's attempt to destroy tumours by the aid of points gave the idea of having recourse to the same means for the ear. He had prepared sticks of chloride of zinc and a little morphia with wheat-flour. These points, dried in the oven, acquire a hardness which allows them to be introduced by pressure into the tissue which it is wished to destroy. Their caustic action is very slightly painful, and they do not penetrate too deeply into the tissues with which they come into contact. The author has thus destroyed, almost without pain, parts of the polypus which excision had not affected, and has daily obtained satisfactory results.

W. DOUGLAS HEMMING.

ASHHURST ON THE OPERATIVE AND CONSERVATIVE SURGERY OF THE LARGER JOINTS, AND ON OPERATIONS FOR DISEASE OF THE KNEE-JOINT.

The ninth volume of the *Transactions of the Philadelphia College of Physicians* contains an article (read March 1, 1876) by Dr. John Ashhurst, junior, [who is best known perhaps for his papers on Obstruction of the Bowels] with remarks by Drs. Packard and Hodge. Dr. Sayre has since intimated his agreement with the views enunciated by Dr. Ashhurst. We thus have four American surgeons of repute agreeing as to the treatment of these troublesome affections. The author of this paper has previously published one on Excisions of the Elbow-Joint. The cases are carefully reported and illustrated with engravings on wood from photographs and drawings. Leaving these as an inducement to surgeons to refer to the original paper, we briefly abstract a few of the practical remarks and suggestions it contains.

As to age, he deprecates operating on very young children, mainly for reasons similar to those which weigh with British surgeons. Except in special cases, he postpones it until at least five years of age has been reached. The great mortality of such

operations also renders them undesirable in persons past middle age. The age from five to ten years is most favourable for excision of the knee-joint. Dr. Ashhurst is a strong believer in constitutional treatment of these joint-diseases. But, whilst admitting that rest and remedies will often supersede the knife in any shape, he yet justly holds that the stage of the disease is of far more consequence than its mere duration. In cases of gelatinous arthritis, he advocates operating earlier than in other forms, on account of its having, apparently, no tendency to spontaneous cure.

Like most British surgeons, he considers excision as a much more serious operation than amputation. The question, as he justly remarks, is not to be settled by mere figures, since the excision cases are selected ones. Yet he has himself lost no case from excision whilst (see table) one of his amputation cases died—this case, however, was one of suppuration and destruction of the knee-joint, and the man had atheromatous arteries, which occasioned difficulty in ligaturing them [? a case for acupuncture]. The cases selected for excision should be free from any visceral disease. He advocates a single transverse incision across the front of the joint, immediately below the patella, the extremities of the wound being carried well backwards, so as to insure free drainage during the after-treatment. [Proposed by Park in a letter to Percival Pott, first employed by Textor, Kempe of Exeter, and Sir W. Fergusson]. For clearing the posterior surface of the condyles, he uses Erichsen's strong probe-pointed knife, with limited cutting edge. For the bones, a Butcher's saw, reversing the blade so as to divide the bone from below upwards. The blade of the saw, thus used, should be so fixed, that its teeth will point backwards, as the force of the arm in sawing upwards is more pulling than pushing.

The condyles should be sawn in a plane, which, as regards the axis of the femur, is oblique from behind forwards, from below upwards, and from within outwards. The tibia should be sawn in a plane transverse to the long axis of the bone, with a slight antero-posterior obliquity to correspond with that of the section of the femoral condyles. Do not remove the whole of the condyles ($\frac{1}{2}$ -inch to 1-inch slice, and even less, according to thickness, is usually sufficient for the tibia). He removes the patella with the extremity of the femur, only using the skin and subcutaneous fascia for a covering, and removing all the other overlying tissues. Thus the suppurating bed left by scooping out the patella is avoided. He uses anæsthetics all through the operation, even to the adjustment of the splint, which he thinks best done with the limbs raised to an almost vertical position. No tourniquet is used, each vessel being secured as divided. He always removes the patella. He uses Dr. Packard's bracketted splint, the brackets being attached on each side to a posterior wooden splint which is interrupted below [*i.e.* under] the knee. (*Trans. Coll. Phys. Philadelphia*, second series, vol. iv. p. 342.) A movable trap fills up the vacancy; it is lifted in and out, and fixed by buttons, instead of sliding. A foot-board has been added by Dr. Ashhurst, and this simple apparatus which has succeeded so well, is figured, as well as a wire-splint on a similar model. Side-splints may be added, but plaster can be attached to the inner bracket, or to both. He advocates the straight position, as unquestionably the best for the stiff limb we expect to get. Whilst the wound is to be dressed daily or as

often as required, the limb should not be disturbed for six weeks if possible. At all events, a fortnight should elapse without any disturbance. He quotes Pénrière's statistics, which give a mortality of over 30 per cent. in 431 cases of excision for chronic disease. The mortality from one to five years was 39 per cent., from five to ten only 15.5 per cent., ten to fifteen gave 19 in the 100, fifteen to twenty-five gave 33 per cent., and all later periods 43 in the 100. Fifty-seven per cent. recovered without further operation, about 1 per cent. after re-excision, and 11 per cent. after (subsequent) amputation. These include the earlier cases, of which many were unselected. Excision of the knee for gunshot injury have been carefully investigated by Cousin, Chenu, Lotzbeck, and Küster. Their figures are as follows : Cousin,

33 cases of total excision gave 28 deaths, or 85 per cent. ; 11 partial cases, 10 deaths, or 91 per cent., or both together over 86 per cent. Chenu's figures (Franco-Prussian war) give 95 deaths out of 102 cases, or over 93 per cent., with a similar preponderance of deaths in the partial cases. Lotzbeck's and Küster's statistics give 73 per cent. out of 66 cases collected by the former, and over 65 per cent. out of 101 cases collected by the latter ; whilst amputation in the lower third of the thigh for gunshot injury only gives 55 per cent. of fatal cases, according to Legouest, and 50 per cent. according to Macleod. Dr. Ashhurst concludes that excision of the knee-joint should be banished from military surgery. The appended table shows the results of the cases given in the paper.

Summary of Dr. Ashhurst's Cases of Excision of the Knee-joint and Amputation in the Thigh for Knee-joint Disease.

I.—EXCISION.

No.	Sex	Age in Years	Nature of the disease and side affected	Duration of disease before operation	Result and duration of treatment after operation	Remarks
1	Male	10	Partial ankylosis of right knee, with recurrent arthritis	Four years	Recovered : five months	Useful limb
2	Female	11	Arthritis of right knee after small-pox	Six years	„ one year	„
3	Male	18	Arthritis of right knee with intra-articular abscess	One year	„ sixteen months	„
4	Male	9	Arthritis of left knee with abscess	Three months	„ four and a half months	„
5	Female	9	Arthritis of left knee, with partial ankylosis	Two years	„ twenty months	„
6	Female	8	Gelatinous arthritis of right knee	Three years	„ still under observation	„
7	Male	5	Gelatinous arthritis of right knee	Over two years	„ six months	„
8	Male	6	Gelatinous arthritis of left knee	One year	„ five months	„
9	Male	5	Gelatinous arthritis of left knee	About two years	„ still under observation	Still wears splints
10	Male	7	Partial ankylosis of left knee, with recurrent arthritis	Two years	Convalescent : still under observation	„ „

II.—AMPUTATION.

11	Male	13	Arthritis of left knee, with necrosis of tibia	One year	Recovered : two and a half months	Death from exhaustion
12	Male	5	Arthritis, with caries of right knee	Eighteen months	Recovered : three weeks	
13	Male	51	Acute disorganisation of the left knee-joint	Five weeks	Died : eight days	
14	Male	13	Gelatinous arthritis of left knee, with caries	Five years	Recovered : seven weeks	
15	Male	18	Arthritis of left knee, with necrosis of tibia	Over two years	„ fifteen months	

Dr. J. H. Packard remarked, as regarded his splint, that he first took an accurate outline of the limb by laying it on a large sheet of paper, and carrying a lead pencil around it, from the greater trochanter on the outer side, up to the perinæum on the inner. If the limb cannot be straightened, the outline should be made on the page by measurement ; then cutting out the piece so defined, it should be tested and corrected by applying it to the under surface of the limb. The shape of the fold of the buttock should be carefully traced. Finally, the exact points should be marked at which the section for the trap for the knee is to be made ; the inner ones should be nearer together than the outer ones, so that the lines may converge somewhat. By this outline the splint should be cut out of stuff proportioned in thickness to the size of the limb ; for an adult a board

about an inch thick is right. The splint should be about three inches longer at the heel than the outline ; and if it be made to extend out three inches on each side, it will serve to keep the limb steadier. For some distance from its upper end, the splint should be carefully bevelled, so as to prevent any pressure of an edge against the skin, and the whole splint should be slightly hollowed from side to side, so as to form, as it were, a very shallow trough for the limb. At the heel, this hollow should be made much deeper, and a longitudinal slit should be mortised to receive the tendon of the foot piece. Dr. Packard fixes the sliding-trap by hooks and eyes on the inner side. The brackets should bulge a little outwards to leave room for swelling. He uses leather side-pieces (laced in front) for thigh and leg.

Dr. H. L. Hodge preferred using strapping instead

of any lacing apparatus. He had two very successful cases in adults: one drives a street-car, the other is a night nurse at the hospital.

W. BATHURST WOODMAN.

HUNTINGTON ON PULMONARY GANGRENE.

In the *Boston Medical and Surgical Journal*, for Oct. 26, Dr. Thomas W. Huntington has published a graduation thesis on thirty-two cases of pulmonary gangrene, compiled from the Massachusetts General Hospital records, from 1857 to 1875 inclusive.

The principal motive prompting to this work was a desire to learn more accurately, if possible, what is the probable course and termination of the disease. There seems to be an impression very generally prevalent that the disease, once fairly established, is progressive in its tendency, and that the lung refuses to set up the line of demarcation so essential to repair and cure. Niemeyer, in writing of this subject, states that recovery 'is a very rare event indeed.' Hertz, in the treatise published in Ziemssen's Encyclopædia, remarks, 'The prognosis is not absolutely unfavourable, as was once supposed.'

Considering the urgent and most distressing symptoms of pulmonary gangrene, unmistakable alike to patient and to attendant, it is not wonderful that such an opinion arose, even if it can be shown to be quite erroneous. It is certainly true that but few and meagre collections of such cases have been made, from which alone an accurate judgment can be formed.

Before proceeding further, it is proper to mention the two forms of the disease ordinarily described, and to indicate that which in this connection is more interesting. Diffuse gangrene, involving from the beginning an extended tract of lung-tissue, is by far the rarer form, and from its nature runs an inevitably fatal course. Cases coming under this head must clearly be discriminated against in estimating the results in the more common and less serious circumscribed gangrene, wherein a limited portion or portions of tissue are implicated, admitting on theory at least the possibility of repair.

Another preliminary statement suggests itself regarding the records of the cases, many of which for various reasons are found to be defective in important details. Thus, in the records of the thirty-two cases the matter of hereditary tendency is entirely ignored in twenty-one. In five there was a history of phthisis, in one of pulmonary gangrene, and in five the 'family history' was reported as good. With regard to habits, a very important item as bearing upon causation, there is no record whatever in twenty six cases, while in six the free use of liquor is noted. Considering the class of patients which forms a large majority of the cases, it is safe to assume that intemperance formed an element in very many of them, so that any deductions from the above data would be quite valueless.

Sex.—Of the thirty-two patients twenty-four were males and eight females. In the same number of cases collected by Lebert and mentioned by Hertz, twenty-two were males and ten females.

Age.—The youngest patient was ten years of age; disease complicated with phthisis and empyema; the result was fatal. The youngest patients without complication were two aged eighteen. Both were discharged 'much relieved,' and with a prospect of permanent recovery. The oldest was sixty-four.

the disease following croupous pneumonia, diffuse; result fatal. The next oldest were two, aged fifty. In one the gangrene was diffuse, following pneumonia; result fatal. The other was a well-marked case of circumscribed gangrene. The patient was discharged, well.

The following is a division of ages according to decades :—

Between	1 and 10	there was	1 case.
"	10 and 20	there were	3 cases.
"	20 and 30	there were	9 cases.
"	30 and 40	there were	12 cases.
"	40 and 50	there were	4 cases.
"	50 and 60	there were	2 cases.
"	60 and 70	there was	1 case.

Total . . . 32 cases.

Employment.—The twenty-four males were distributed among eight different callings. By far the greater number were inevitably subjected to extremes of temperature and to wet. Thus, twelve were common labourers, four were seamen, and the remaining eight were variously occupied. The eight females represented but three different callings: five were domestics, two were housewives, and one was a seamstress. In brief, twenty-one of the thirty-two cases can be said to have had exposure as an element in causation.

Duration.—No accurate statements can be made upon this topic, except in those cases which terminated favourably or fatally while under observation, as there are no subsequent data concerning those discharged during the progress of the disease. Of the eleven fatal cases, the longest was in progress ten months, the shortest one month; average duration, 3·3 months. Of the seven cases of recovery four had a duration of seven months, two of three months, and one of four months; average duration 5·3 months.

Causation.—Little remains to be said upon this topic, further than the general statements made under ‘employments’ and ‘habits.’ It is interesting, however, to note that of the eleven fatal cases, in seven the disease was preceded by croupous pneumonia, in one by cancer of œsophagus (gangrene caused by mechanical pressure), and in one by empyema and phthisis. In both the last cases death was due in large part to the original disease.

Results.—Seven cases were discharged well; six much relieved (these with proper care and favourable circumstances doubtless proceeded to ultimate recovery); three cases were temporarily relieved; five were not relieved, two of which were in the hospital but for a brief period, and were not treated; eleven cases terminated fatally. Several of the above statements will be subject to further comment under the following topic.

Complications.

Cases with complication	10
Cases without complication	22
Phthisis as a complication occurred in	8
Empyema " " " "	1
Cancer of œsophagus " " " "	1

In seven of the cases without complication gangrene followed pneumonia, and was diffuse. The termination was fatal.

Leaving the latter out of the discussion, according to the original plan, the following statement can be made. Of the fifteen cases without complication, five were well, six much relieved, one was relieved temporarily, three not relieved, none died. In other words, among the cases of circumscribed gangrene,

there were eleven favourable and four unfavourable terminations.

On the other hand, of the complicated cases, four died, two were not relieved, two were temporarily relieved, and two were cured of gangrene. That is, two terminated favourably, so far as the disease under consideration is concerned, and eight terminated unfavourably.

Summary of results and complications per cent. :

	Without Complica- tions.	With Complica- tions.
Terminated favourably . . .	73·3	20
Terminated unfavourably . . .	26·6	80

ANATOMY AND PHYSIOLOGY.

STROGANOFF ON THE PROCESS OF OXYDATION IN NORMAL AND ASPHYXIATED BLOOD.—N. Stroganoff (Pflüger's *Archiv*, Band xii., *Centrabblatt für die Medicinischen Wissenschaften*, no. 28) has endeavoured to decide the question.—1. *Whether the Blood of an Asphyxiated Animal still contained Oxy-hæmaglobin.*—He placed between two glass plates the completely isolated jugular vein, or the carotid of rabbits, and compressed them so that a spectroscopic investigation was possible. The vessel was protected from contact with the air. It was invariably found that the blood, even at the last moment of the last cardiac contraction always contained oxyhæmaglobin.

2. *On the Amount of Oxygen in the Lungs during Asphyxia.*—The composition of the air of a closed space in which the animal, in consequence of want of oxygen (the carbonic acid was absorbed) was asphyxiated, was estimated when the respiratory movements ceased. As the mean of four experiments, the amount of oxygen in the air at this moment was 3·54 per cent., agreeing well with previous results. If one assume, that the blood had absorbed the same amount of oxygen from this blood as in normal respiration, then the amount of oxygen in the air within the lungs would be 2·73. The complete cessation of all respiratory movements is regarded by the author as the second stage, and at once the air still remaining in the lungs was extracted by means of a mercurial air-pump. The analysis gave as the mean for the oxygen of this air 2·337. If the air were taken from the lungs after cessation of the movements of the heart, the amount of oxygen was only 0·403 per cent.; almost all the oxygen, just to a trace, was absorbed by the blood.

3. *On the Capacity of Asphyxiated Blood to absorb the last Traces of Oxygen from the Air in the Lungs.* Asphyxiated blood taken from an animal after cessation of the respiratory movements, was shaken with a quantity of air very poor in oxygen, and then its composition ascertained. It was shown that the blood absorbs oxygen, even when the latter is only present to the amount of 1 per cent. or less. To determine whether this is also true of the lungs, Stroganoff pumped out the air from the lungs after cessation of the respiratory movements, and introduced air of known composition instead. Here also oxygen disappeared from the air. The amount of oxygen introduced with the air, in one case was 1·289 cubic centimetres; the remainder 0·747. The blood in the lungs therefore absorbs oxygen from the air in the lungs, even after cessation of the respiratory movements, so that not a trace of oxygen is left.

4. *On the Extent of the Oxydation Process in Normal and Asphyxiated Blood.*—In order to estimate this in asphyxiated blood, it was shaken with a sufficient quantity of atmospheric air, and the amount of oxygen remaining, and that of hæmoglobin determined. If the amount of oxygen absorbed is greater than corresponds to the quantity of hæmoglobin, then oxygen must have been used for the oxydation of reducing substances in the blood. As asphyxiated blood is never quite free from oxygen—according to Pflüger, 1·75 volume per cent.—this also must be taken into consideration. The experiments were repeated in the same way with arterial and venous blood. Even arterial blood absorbs oxygen, as Pflüger had already shown, to the extent of 1·066 to 1·295 cubic centimetres for 100 cubic centimetres. Stroganoff assumes that the blood, in virtue of its hæmoglobin, is completely saturated with oxygen. The asphyxiated blood invariably absorbs considerably more oxygen than corresponds to its amount of hæmoglobin, to the extent of 4·93, 2·84, 3·31, and 2·34 cubic centimetres for 100 cubic centimetres of blood. If one assume the amount of oxygen contained in it as = 1·75 volumes per cent., we have the mean 5·10 volumes per cent. as the expression of the reducing substances present in the blood. The author then deducts the amount of oxygen required by the blood for the oxydation = 1·18 cubic centimetres, and arrives at the number 3·927 cubic centimetres of oxygen. For all the details and data of the experiments we must refer to the original.

BUDGE ON THE LYMPHATICS OF THE LIVER.—A. Budge (Ludwig's *Arbeiten*, Band x.) from his injection experiments draws the following conclusions regarding the perivascular spaces of the liver. A closed system of lymphatics exists in the liver, and is in most intimate relation to the venous blood-vessels. Within the lobules there are simple lymphatic sheaths around the blood-capillaries, which prevent the direct contact of the hepatic cells with the blood, so that any exchange between these can only take place through the medium of the lymph. Just as the blood-capillaries at the margin of the lobules unite into larger trunks, so the lymph-sheaths pass into lymphatics, which are placed in the walls of the veins, and by means of the interlobular vessels pour their contents upwards into the lymphatics of the diaphragm, and downwards into those of the hilus.

W. STIRLING, D.Sc., M.D.

ALLEN ON THE ANATOMY OF THE PERINÆUM.—Dr. Harrison Allen (*Transactions of the Philadelphia College of Physicians*, vol. ix. p. 114), says: The perinæum, used in the sense of that region which occupies the inferior outlet of the pelvis, is composed of two distinct elements, the splanchnic and integumental.

The splanchnic is represented in the pelvic fascia; the integumental in the external sphincter and transverse perineal muscles, superficial fascia, fat and skin. It will be seen that the pelvic fascia is modified subperitoneal connective tissue. It should be described as distinct from the obturator fascia, which extends the entire length of the pelvic portion of the internal obturator muscle, terminating at the tuberosity of the ischium, where it is continuous through the falciform process with the great sacro-sciatic ligament. The continuity of these structures is of

some significance when we learn that this ligament, as it is called, is, in fact, little else than a fascial extension upwards of the biceps flexor muscle, and is made tense when the thigh is flexed on the trunk, and relaxed when both the femur and innominate bone are in the same line. Two conclusions can be drawn from these premises. (1) The biceps flexor, while aiding the semi-membranosus and semitendinosus muscles in maintaining the erect position, has also an important function, not enjoyed by them, of making tense the sacro-sciatic ligament in flexion of the hip-joint. (2) The tension of the ligament secures tension of the obturator fascia. Now the fascia, in this way made tense, yields an effective fixed point to the levator ani muscle. When the use of this muscle in the act of defecation is considered, viz., to support the rectum, and to guide the direction of the pressure from above, it will be seen that the squatting position is the most natural one to assume in defecating, and that any interference with the play of the biceps over the tuberosity of the ischium impairs the efficiency of this act. The privy seat, which fixes the tuberosity in defecation, and the habit of relaxation of the parts above described, acquired by resorting to this questionable accessory of a modern dwelling, may be looked upon as related causes of many phases of passive congestions of the pelvic organs, and particularly of those leading to internal hæmorrhoids.

[The reporter, whilst freely admitting the cogency of Dr. Allen's arguments, begs to observe that constipation is no modern ailment, since Catullus sang in hendecasyllabic verse, to Furius, in this wise :

Nec toto decies cacas in anno.—*Rep.*]

W. BATHURST WOODMAN.

BERNARD ON THE INFLUENCE OF ETHERISATION ON VITAL PHENOMENA.—At the meeting of the Société de Biologie de Paris on October 28, Dr. Claude Bernard gave an account of some new experiments he had made on this subject (*Progrès Médical*, November 4). In a previous communication he had shown that anæsthetics suppress, during their action, some vital phenomena, movements of the sensitive plant, germination of cresses, fermentation of beer-yeast, etc. His recent experiments have been made on the lower animals—small eels. It is known that these animals when dry lose all movement, and remain inert, but it is sufficient to place them in water to see them resume their movement. If we plunge them in pure chloroformed water the movements disappear, and immersion in water will not bring them back; the animals are dead. But if we plunge them into a chloroformed solution diluted with its weight of water the movements cease, the animals fall inert. On withdrawing them from this liquid to place them in water, however, the movements are renewed; in this the anæsthetic action has not been sufficiently strong to kill the animal. Etherised water acts in a similar manner, but with less intensity than the chloroform. If these facts be considered together with those previously established, we must conclude that anæsthetic agents are, so to speak, re-agents on the vital phenomena suspended during etherisation.

How do the anæsthetics act? Their action is exerted on all the elements as well as on the nervous system, which is the first affected. The exact nature of the phenomena must still be sought; nevertheless it seems probable that it is the protoplasm which is modified by the anæsthetic agent.

It has been remarked, in fact, that the muscles during etherisation become opaque, recovering their transparency when the etherisation ceases. The same phenomenon was present in the above-mentioned animals during and after etherisation.

In the discussion which followed, M. Berthelot asked whether this action of the anæsthetics might not be explained as a chemical modification. In fact, they coagulate the albumen and the myosine. Besides, the existence has been found in the sensitive plant and in the seeds of vegetables of a substance analogous to the proximate principles of the cerebral substance. It is possible that anæsthesia in vegetables and animals may be due to a chemical modification of these proximate principles.

W. DOUGLAS HEMMING.

RUTHERFORD AND VIGNAL ON THE BILIARY SECRETION OF THE DOG.—A second series of experiments on this subject by Professor Rutherford and M. Vignal are partly described by them in the *Journal of Anatomy and Physiology*, vol. xi. part 1, pp. 61–86. The methods employed were the same as in the first research. The substances were in each case introduced directly into the duodenum of a fasting dog, and the flow of bile was estimated every fifteen minutes. Small doses of curara were given to prevent muscular movements, but anæsthetics were not administered on account of their disturbing influence on the biliary secretion. The different substances experimented with, and the results obtained with them, are shortly as follows.

Euonymin, an impure resin obtained from the bark of *Euonymus atropurpureus*, employed in America and reputed to be a tonic, hydragogue, cathartic, diuretic, and antiperiodic, was used in two experiments. 1. Five grains, mixed with a small quantity of boiling water, powerfully stimulated the liver. 2. At the same time there was only a slight increase of intestinal secretion; hence its purgative effect in the human subject may be chiefly due to increased 'secretion of bile.' The authors think this substance worthy of far greater attention in practical medicine than it has received hitherto.

Sanguinarin was also employed as a resin. It was stated by Tully in 1830 to be a very decided cholagogue in small repeated doses, and recommended by Mothershead of Indianapolis as an excitement of the liver when given in small alternative doses. Two experiments were made. 1. In one experiment three grains, in another one grain, mixed with bile and water, powerfully stimulated the liver. 2. It rendered the bile more watery, nevertheless caused the secretion of more biliary matter in a given time. 3. The secretion of the intestinal glands was slightly increased. The statements of the above writers are therefore deserving of attention.

Iridin, a resin prepared from the root of *Iris versicolor* (American blue flag) 'is thought to unite cholagogue and diuretic with aperient properties' (Wood and Bache). Two experiments were made. 1. Five grains mixed with a little bile and water very powerfully stimulated the liver. It is not so powerful as large doses (four grains) of podophyllin, but 'it is more powerful than euonymin.' 2. It is a decided stimulant of the intestinal glands. Its irritating effects on the intestine mucous membrane are decidedly less than those of podophyllin, (which corresponds to a statement concerning it made in the *Lancet* for 1872), while 'the purgative effects are greater than in the case of euonymin.'

Leptandria, a resin prepared from the root of the American plant, *Leptandria Virginica*, or *Veronica Virginica*, has been lauded as a cholagogue and tonic, and is now much employed. Two experiments were made. 1. When mixed with bile it stimulates the liver, but very feebly. It excites the liver to secrete bile having the ordinary composition. Like 'podophyllin,' it produces scarcely any effect unless the biliary solvent be present. 2. It is a feeble stimulant of the intestinal glands.

Ipecacuan. Four experiments were made. 1. Sixty grains of powdered ipecacuan, mixed with a small quantity of bile, powerfully stimulated the liver. Even 3 grains had an effect on a dog weighing 6·8 kilogrammes, very nearly as great as the effect of 60 grains on a dog weighing 27·2 kilogrammes. 2. The bile secreted under its influence was normal as regards the biliary matter proper. 3. No purgation was produced, but there was an increased secretion of mucus in the small intestine. It is certain, the authors think, that this substance has the power of stimulating the secreting apparatus of the liver. These experiments, they think, will lead to new speculations regarding the pathology of dysentery.

Colocynth. Two experiments were made. 1. It is a hepatic stimulant of considerable power. It renders the bile more watery, but nevertheless increases the secretion of biliary matter. 2. It is a stimulant of the intestinal glands.

Falaf. Three experiments were made. 1. It is a hepatic stimulant of considerable power. It renders the bile more watery but at same time increases the secretion of biliary matter. 2. Its effect on the liver is, however, far less notable than its hydragogue cathartic effects on the intestinal glands. These experiments illustrated a fact often witnessed by the authors, that severe purgation diminishes the secretion of bile.

DUCKWORTH ON A SMALL APERTURE IN THE SEPTUM VENTRICULORUM NEAR THE APEX OF THE HEART.—Dr. Dyce Duckworth (*Journal of Anat. and Phys.*, vol. xi. pt. i. p. 183) describes a case of this deformity, which is rare on account of the unusual situation of the opening. It was large enough to admit a crowquill, and situate at the junction of the middle and lower thirds of the septum, near the posterior part. The object of it, a male child, born at full time, was cyanotic at birth.

E. CRESSWELL BABER, M.B.

GULLIVER ON THE COMPARATIVE PHOTOGRAPHS OF BLOOD-DISCS.—Mr. G. Gulliver, makes some interesting remarks on this subject, in the November number of the *Monthly Microscopical Journal*. After disabusing the minds of his readers of any attempt on his part of analysing the relative merits of American microscopists in this department, he proceeds to point out that the corpuscles of one species of the vertebrate class seen in a single individual, differ so greatly in size, that the average dimension cannot be obtained with absolute certainty, whilst in many mammals the blood-discs are absolutely indistinguishable from those of man. The blood of most ruminants and most feræ can be readily recognised from that of man, whilst the corpuscles remain regular, but this is dubious with regard to the blood-spots which come before medical jurists. He considers the efforts of Drs. Richardson and Mees, and Professor Wormley, as highly praiseworthy, and the

results already obtained as creditable to American micro-photography.

SATTERTHWAITE ON THE STRUCTURE AND DEVELOPMENT OF CONNECTIVE SUBSTANCES.—In the Nov. issue of the *Monthly Microscopical Journal*, Dr. Satterthwaite of St. Luke's Hospital (New York) contributes the results of his inquiries in this direction.

The writer first considers the neuralgia, and points out the fact that the corpuscular element has not been definitely described. He recommends as a method of examination the immersion of the brain or cord in a 5 per cent. solution of bichromate of potash, or Müller's fluid, for a few days afterwards in alcohol until perfectly hard. The sections are stained with hæmatoxylin, mounted in glycerine, and teased with needles. He groups the corpuscular forms met with here under three categories, viz., 1. Ganglionic cells; 2. Lymphoid cells; 3. Small irregularly branched corpuscles. Passing on to the connective elements of tendon, the writer regards both the silver and gold method as most valuable for the demonstration of the nuclei, the epithelioid layer of the tendon bundles, and the fibrillated structure of older tendons. Dr. Satterthwaite next directs attention to the adipose tissues, their demonstration, and the nature of the evidence that fat-corpuscles are transformed corpuscles of the fibrous tissues. The nature of the lymphoid corpuscles described by Waldeyer, is briefly touched upon by the author, but no definite conclusion is arrived at. Intermuscular tissue he regards as a soft, structureless, homogeneous matrix, in which oval, flattened, plate-like bodies are imbedded, closely related to the neighbouring elastic network. In the connective of the kidney the same flat-like bodies are recognised, but the matrix here presents great difficulties in the determination of its fibrillated or non-fibrillated structure. As regards the corneal tissue, the writer directs attention to the ambiguous term corneal corpuscles, as lately employed, and proceeds to show that the corneal tissue really consists of irregularly shaped corpuscles in well defined areas, the corneal spaces of Recklinghausen; that these spaces may intercommunicate by their radiating processes, and that the intercellular material is generally regarded as separable into distinct fibrils. The writer relegates to a separate list the elastic tissues on the grounds of their dissimilarity to the tissues previously considered, in both their microscopical and their chemical nature. Excluding the elastic tissues, the writer next takes in review the elementary constituents which determine the affinity between the diversified structures included under the term connective. The flattened, plate-like cell is minutely described, and the special value of logwood in its demonstration is alluded to. Heitzmann's theory with regard to the connection of connective corpuscles by their radiating extensions is shown to be subject to numerous exceptions. The second element—the lymphoid corpuscle—is described as pale, uncoloured by hæmatoxylin, and often closely connected with the plate-like corpuscles. With these are found cells four or five times as large as the lymphoid bodies, with oily contents. The writer regards the plate-like bodies as forming a partial investing sheath for the fibre-bundles, the processes of the former frequently anastomosing. He differs from the views of Klein with regard to adenoid tissue being formed of 'netted cells.'

The developmental history is next traced out, ob-

jection being taken to the free use of the term spindle-cell. This term is stated to be applied frequently to connective bodies which are really but thin ribbon-like portions of intercellular substance, upon which a flattened corpuscle is often seen, which may be displaced by pressure on the cover-glass. The so-called spindle-cells of some fibro-recurrent tumours are thus explained. The stages of corpuscular development begin with the round body soon becoming flattened and possessing a broad envelope. An external delicate investment now forms the starting-point for the intercellular growth. The plate-like bodies can at first be brushed out of their niches, but, eventually they become smaller, disposed in rows, whilst their envelopes shrink and recede from each other as fibrillation proceeds. The paper, which forms but the second part of a communication made to the Biological Section of the New York Academy of Sciences, is illustrated by several plates of the structures described.

BEVAN LEWIS, L.R.C.P. Lond.

TURNER ON THE PLACENTATION OF THE CAPE ANT-EATER.—Professor Turner (*Journal of Anatomy and Physiology*, vol. x. part iv.), finds that the placenta of orycteropus is not discoidal, as described by Professor Huxley in his *Introduction to Classification*, but zonary, as in the carnivora, pinnipedia, hyrax, and elephas. It differs from these, however, by occupying a relatively larger extent of the whole length of the chorion and uterus. In the bitch and cat the placenta occupies about one-fourth; whereas in orycteropus it occupies a half or more of the uterus and chorion. The inner surface of this broad and nearly uniform band is, as in the grey seal, convoluted; and its margins are overlapped from a quarter of an inch to an inch by the uterine mucous membrane.

The umbilical cord is made up of two veins, two arteries, and in the centre a fine tube, believed by Professor Turner to be the undoubted remains of the allantois. The vessels are not only distributed to the placental part of the chorion, but numerous branches pass to the non-placental area, and form there a dense capillary plexus.

The two specimens having been long in spirit, it was impossible to make out whether the placenta is deciduate or non-deciduate. In one of them the placenta was easily separated from the uterine wall. The external surface was less convoluted than the internal, and the part of the chorion from which it was removed had a velvety appearance; but differed from the chorion of the mare in having the villi more uniformly diffused in sinuous ridges.

On a more minute examination, amongst other points of interest Professor Turner was able to make out the glands and crypts of the uterine mucous membrane—the crypts, as in many other mammals, greatly exceeding in number the glands. The paper concludes by alluding to the fact that in the edentata there are examples of every form of placentation except the cotyledonary. J. C. EWART, M.B.

CURSCHMANN ON THE RELATION OF THE SEMI-CIRCULAR CANALS TO THE BODILY EQUILIBRIUM. H. Curschmann (*Archiv für Psychiatrie* Band v. and *Centralblatt für die Medicinischen Wissenschaften*, no. 21) experimented on pigeons. The anatomy of these structures, and the method of operating, are to be found in the original. It is to be specially noticed that Curschmann, in operating, tried to avoid as

much as possible injury to the bones of the skull and the osseous canals, and only to destroy the membranous canals.

If on one side a large piece or the whole of a horizontal canal be destroyed, as long as the animal is at rest nothing special is to be observed; but the animal is more sluggish and is not able to fly. If the animal be made to move, it makes a circle towards the opposite side. Further, irregularity in the use of the left leg is detected, which is placed down awkwardly. The animal is also awkward in feeding. Nothing abnormal is noticed regarding the position of the eyes. Further investigations showed that the muscular force on the injured side was unimpaired; but the capacity for co-ordination appeared to be affected on the one side. The better co-ordinated muscles of the intact side, when the animal moves, exert their superiority and incline the animal to the affected side. There is no internal impulse to these movements.

If the horizontal canal be destroyed on both sides, even then nothing beyond a little sluggishness is to be observed. In moving, however, the animals (which when at rest keep the head quite steady) execute circles first to the one side and then to the other. Then the head begins to move in a horizontal direction from one side to the other. To take food is, under these circumstances, impossible. The abnormal position and movement of the head and the disturbance in the equilibrium of the body are co-ordinated, but the former are not the cause of the latter. The capacity of flying is quite lost in such animals; the proper muscular force of the wings however is intact. If only section of one horizontal canal be practised, the symptoms are only distinguished in degree from those of the severer operation; they gradually become less perceptible, and at the end of the first week may have disappeared entirely.

The results of injuries to both vertical canals are essentially the same. In extensive destruction of the canals on both sides, the animals when at rest are extraordinarily sluggish; while moving, the body vibrates first forward then backward; they do not run in a circle, but run rapidly forwards, and then equally so backwards, and fall forwards. In moving forwards powerful efforts are made to prevent the falling forwards. In such movements, the head vibrates from above downwards; the peculiar torsion of the head described by Goltz also occurs, but is not constant, and the author shows that it is to be ascribed to injury of the dura or cerebellum. That the disturbance in the equilibrium of the body is caused by the abnormal position of the head, as maintained by Goltz, is rejected by the author, for in unilateral lesion of the canals the head exhibits no movements, whilst they appear characteristically in the body. It is also to be noticed that, after one of the vertical canals was injured on both sides, a diminution of the pathological phenomena occurred in two experiments, which never occurred in bilateral injury of both horizontal canals.

On injuring only the vertical canal on one side, the phenomena are few. The position of the head and body at rest are normal; that of the head is not even changed during movement; the capacity for flying is relatively little interfered with. In running, the foot of the operated side is awkward; some animals fall forward or backward, but generally with a tendency to stumble towards the injured side. The phenomena may all disappear early and completely.

If all three canals be destroyed on one side, little

abnormal is observed during rest; while running there is a combination of *mouvements de manège* and oscillations of the body forwards and backwards.

In bilateral destruction of all three canals the movements are quite irregular, and the head is tossed in an irregular manner in a circular direction. While sitting at rest, the position of the head and body are again normal; so that, even after complete destruction of all the membranous canals, complete loss of the bodily equilibrium does not ensue, nor is hearing thereby abolished.

PATHOLOGY.

MITCHELL ON LOCAL INJURIES TO NERVES AND THEIR TROPHIC CONSEQUENCES.—At the meeting of the Philadelphia College of Physicians on May 3, 1876, Dr. Weir Mitchell read a paper, which appears in the ninth volume of their *Transactions*, pp. 115-138, illustrated with a chromolithograph and twelve diagrams. Case 1 he regards as almost unique. It was given him by Dr. Crawford of Wilkesbarre. James Graham, a night watchman, was wounded by the accidental discharge of a pistol, January 29, 1871. The ball entered the front of the arm, passing obliquely downwards and backwards through the belly of the biceps, and made its exit at the back of the limb, $1\frac{1}{2}$ inches nearer the elbow than its point of entrance. Profuse hæmorrhage was controlled by pressure. He did well till February 9, when secondary hæmorrhage occurred. Pressure stopped it till next day, and acupuncture for eight days more, but twenty-four hours after removing the needle he bled again. An incision at the point of entrance revealed a false aneurism of the size of a hen's egg, on the brachial artery, from a small wound in its posterior aspect, communicating with the (shot) wound. It was emptied, and the artery ligatured above and below. Slight numbness of the fore-arm and hand had been noticed from the very first. This and the pain steadily increased. Abscesses formed, and he died of pyæmia on the forty-ninth day (March 19); the surroundings were very unfavourable to health. Examined after death, the brachial artery had become closed above and below, but the anastomotic circulation was never properly established. The surface of the humerus was found to be denuded of its periosteum for an inch or more in extent, at a point corresponding to the line of the wound, and a portion of the bone had evidently been detached. No appearance of repair could be seen. A longitudinal portion of bone was found attached to the sheath of the median nerve, at a point in close proximity to the original wound. A portion of this bony mass, with the nerve attached to it was exhibited. One end ($\frac{1}{3}$ inch long) was removed in making a section for the microscope. It was found that the bone was firmly attached to the nerve-sheath, and a microscopic section gave evidence that this fragment of bone was in process of growth (the comparative size of the canaliculi, those near the surface being larger than those near the centre, seems to warrant this). Verneuil (page 112

of Dr. Mitchell's book on 'Injuries of Nerves') reports a case of a fragment of periosteum carried away by a ball, and lodging on a nerve, where it developed bone. (See also page 216, for wound of the inframaxillary branch of the fifth nerve by splints of bone from gunshot wound.) The next case (Case 2 of this series) is one of injury to the ulnar, radial, and median nerves by a compound fracture of the forearm, in a boy aged nine, close to the elbow. On February 27, 1874, nearly eight months afterwards, there was a cicatrix four inches long down the middle of the forearm. Extension of the forearm was limited one half; pronation and supination were lost; the wrist-motions were lessened by joint-lesions and loss of power. The fingers were set in the form of a claw, with slight power to extend the second and third phalanges, but no other motion. Sensation to touch was entirely lost in the median territories, deficient in the ulnar region, and altered in the radial region. The face of the lower half of the forearm was hyperalgesic here, as in the whole palm, parts of the fingers, and over most of the dorsum; every touch was felt as pain of a burning character. There was also a constant torment of similar kind. The hand-muscles were wasted, and the thumbs rotated outwards, so that the nail lay in the same plane with the finger-nails. The whole hand, especially the fingers, was dusky red, swollen, and as smooth and glossy as if polished. [Sir James Paget appears to have been one of the first to call attention to this smooth glossiness of skin in nerve-lesions.—*Rep.*] The nails were curved like turtle-shells in all directions, roughened, dark, and elevated, as if by the overgrowth of subjacent tissues; the matrix in all of them was separated from the nail, and ulcerated. On the back of the hand was an irregular stellate deficiency of pigment, not due to original defect or to a scar. The hand and fingers were blistered by successive blisters, to remove tenderness. Then faradisation and *massée*-ing the hand, and cautious moving of the joints effected, in a year, an almost perfect cure. This is the case to which the coloured picture belongs. Five cases of injuries to the median nerve, with diagrams of the tactile sensibility, are also given; complete loss of sensibility is shown in deep, almost black shading, and a partial loss in lighter shading, whilst the distances are expressed in parts of an inch. In some of these cases bullæ, ending in deep ulcers with well-defined edges, formed (Cases 3, 4, 5). In another case an abscess resulted. 'We may have,' says Dr. Mitchell, 'from injuries seemingly alike, joint-diseases, or glossy skin, or herpetic eruptions, or circumscribed blisters, or deep ulcers, or altered nails, œdema, atrophy, or hypertrophy. The circumstances which regulate the production of these several pathological states are as yet unknown to us. At present we can only confess our ignorance.' [The reporter has noticed that the finger-nails of patients suffering from general paralysis of the insane have in several instances been affected in the way described by Dr. Mitchell. There has, however, been some doubt, in most of the cases, whether it were simply a nerve-lesion, or due more or less directly to syphilis.—*Rep.*]

MEDICINE.

DOLORIS ON A CASE OF THROMBOSIS OF THE ANTERIOR CORONARY ARTERY, WITH RUPTURE OF THE HEART.—At one of the meetings of the Anatomical Society of Paris in June last, M. Doloris read the following case, which was under the care of M. Bouchard at Bicêtre. (*Progrès Médical*, Nov. 11). A patient, aged seventy-five, was admitted on May 27. On admission he was in a semi-delirious state, which prevented any clear history from being obtained ; he complained only of a vague pain in the epigastric region, spreading from the base of the thorax towards the hypochondriac regions ; the pain was increased by movement, and this increase of pain was accompanied by dyspnœa. At the time of admission the pain was not great ; the patient, perhaps on account of his semi-delirious condition, complained little, and pressure caused little distress. The face was flushed, the pulse small and frequent, the radial artery atheromatous, the temperature normal to the hand, the tongue moist.

Auscultation of the chest gave signs of chronic bronchial catarrh ; in the heart were heard bruits, distant, not well marked, and remarkably irregular ; a series of rapid beatings was succeeded by a series of very slow ones. In fact the symptoms were those of an old heart, whose orifices were altered and whose action was affected by degeneration of tissue. Percussion gave increased dullness in the cardiac region, leading to the supposition of hypertrophy, which agreed well with the presumed lesions on the one hand and with the chronic respiratory trouble on the other.

Retrospective information gleaned from different sources enabled the history to be completed. The attack commenced about eight days before, and was marked simply by pain ; nothing particular was heard about the heart by the 'interne' who was called, except some irregularity and a little hypertrophy. In the course of the day the pain became less, but towards evening syncope came on. From this time the appetite diminished, pain appeared from time to time as a very uneasy oppression in the epigastric region, but the patient did not keep his room during the eight days following the attack. The evening of his admission he was seized with delirium. The 'interne' found nothing very serious about the heart or lungs ; there was a kind of malaise and generally ill-defined discomfort. The temperature was plainly febrile. The patient was admitted, and was found at the evening visit in the condition previously mentioned. During the whole of the night the pain was violent and the delirium intense. In the morning slightly calmer, but still marked agitation all the next day (May 28). During the next night pain and dyspnœa reappeared,

with increased delirium. The patient talked incoherently, constantly changed his position, and wanted to get up.

May 29.—He complained less, and seemed better. About eight o'clock in the evening the patient died suddenly.

Necropsy.—The stomach was very much thinned about the greater curvature ; it was of reddish colour, with softening of the mucous membrane. The lungs were healthy, slightly diminished in volume, apparently from compression ; there was some bronchial dilatation, and chronic inflammation of the bronchial mucous membrane. In the kidneys was some fatty degeneration. In the encephalon, multiple lesions were disseminated in the motor centres, cortical portion, etc. An enormous blood-clot entirely filled the pericardial cavity ; externally the clot appeared homogeneous, smooth, and adherent only at a few points to the parietal surface of the pericardium. At these points there existed on the surface of the serous membrane a thickish, yellow, somewhat adherent exudation, composed of fibrine and some nuclei ; around and below the exudation the pericardium was injected. On the cardiac aspect the clot was lined by a thick false membrane, not adherent to the cardiac wall, and entirely composed of fibrine. The visceral pericardium was inflamed in places, and was lined with a layer of fatty tissue. At the level of the apex of the heart, on the left edge, was a linear rupture extending obliquely from above downwards, and from left to right. This tear occupied the whole thickness of the cardiac wall ; all around the cardiac tissue was blackened and softened, and the muscular fibres were inflamed. Examined from the ventricle, the rupture appeared only as having raised a kind of clot forming a sort of mouth in the conical extremity of the left ventricle. Around the internal clot the cardiac tissue was softened.

On dissecting the anterior coronary artery, there was found, at a point corresponding to the infiltrated zone, an arterial branch about two millimètres thick, obliterated for a length of seven or eight millimètres by a hard thrombus of a yellowish white colour, which completely filled the vessel. The thrombus appeared to be composed entirely of fibrine.

Remarks.—In the existence of this clot and the obliteration of so considerable an arterial branch we find the explanation of the cardiac softening and rupture. How and when was this rupture produced ? The organisation of a part of the interpericardiac clot, and the traces of inflammation of the serous membrane, seem to say that the rupture did not take place all at once, and that it commenced on the outer surface of the heart, whilst the internal surface sustained on the ventricular aspect by the internal clot, produced by surrounding myocarditis, was broken by a last effort which marked the moment of death. Did the syncope correspond with the period of formation of the thrombus ? Probably.

W. DOUGLAS HEMMING.

HAMILTON ON NEUROSES FOLLOWING ZYMOTIC FEVERS.—Dr. Hamilton, of New York, draws attention, in a communication to the *New York Medical Record* for October 28, 1876, to the chronic nervous affections which not unfrequently follow variola (including varioloid and varicella) and cerebro-spinal meningitis, and to the permanent muscular contractions, tremors, pareses, and mental weakness which occur as sequelæ of scarlatina and other fevers. Cases of neuralgia and more or less general paralysis

are cited from other writers, and several original ones are added, including one of partial paraplegia in a young man after an attack of enteric fever, in which the author recommended iodide of potassium in addition to ergot and the use of the actual cautery. With respect to the treatment of these post-febrile neuroses, he adds, 'very little can be done. I have great faith in iodide of potassium and belladonna. The actual cautery, not used superficially, but for the production of ulcers on the back of the neck and between the shoulders, sometimes relieves the patient, but at best the improvement will be of short duration in the majority of cases.' [With less energetic treatment a more favourable prognosis seems justified by experience in this country.] Dr. Hamilton refers particularly to Dr. Edward Long Fox's work on the pathological anatomy of the nervous centres, and concludes with the following list of writers on the subject, to which may be added those of Vulpian, Westphal, and Lockhart Clarke, also quoted by the author, and well known in this country: Gallup, 'Sketches of Epidemic Diseases in the State of Vermont,' etc., Boston, 1815; *American Psychological Journal*, May, 1876; *Chicago Journal of Mental and Nervous Diseases*, vol. i. p. 171; E. L. Fox, 'Pathological Anatomy of Nerve Centres,' pp. 360, 371, 372; Goss, *Boston Medical and Surgical Journal*, May 8, 1873; J. J. Putnam, *ibid.* August 7, 1873; Webber, *ibid.* May 22, 1873; Eulenburg, 'Funktionelle Krankheiten,' Berlin, 1871; Rosenthal, 'Nervenkrankheiten,' Erlangen, 1870; *Berliner Klinische Wochenschrift*, November 18, 1872; *Allgemeine Medicinische Zeitung*, December 7, 1872; Schmidt's *Fahrbücher*, No. I., 1873; *Centralblatt für die Med. Wiss.*, February 15, 1873; *Archives de Phys. Norm. et Path.*, January, 1873; Troussseau, 'Clinical Medicine,' translation of third edition, vol. i. p. 66.

DISEASES OF CHILDREN.

APPENRODT ON PURPURA HÆMORRHAGICA IN EARLY INFANCY.—Two cases of this disease, attacking children in the first year of life, are recorded in the *Deutsche Medicinische Wochenschrift* for September 30. The hygienic conditions appear to have been good in both. The first case occurred in a very rachitic child, aged twelve months. The eruption appeared in one night, and involved every part of the skin, except the soles and palms. The mucous membrane of the mouth and conjunctiva remained free. On the next day, the motions were blackened. On the seventh day the spots disappeared as suddenly as they had come. Recovery was complete. The second case was that of a well nourished child aged nine months. When but fourteen days old, he was attacked with whooping cough, which lasted fifteen weeks. He had been under treatment about a month for 'inward convulsions,' when suddenly, on May 9, epistaxis, hæmatemesis, and purpura set in. The eruption showed itself in the same parts as in the other case; but, with the addition of the lips, gums, tongue, palate, and pharynx. The urine was said to have been red. The child was semi-comatose, but groaned when moved; the eyes were half opened and directed upwards; pulse and respiration quickened. On May 11 the child had not slept; it groaned frequently; the body was drawn up. The breast was still taken eagerly. The urine was blood red, but without clots. The stools were blackish green (the child had taken calomel). The spots were more numerous. Pulse 144, soft and full. On May 12 the child was much the same, but more restless; by the evening, many of the spots had disappeared. They were no longer visible on the mucous membrane. Pulse small, 168; temperature, 103.5. Death took place at three o'clock the next morning, after evacuation of a large quantity of clear urine. The examination *post mortem* was limited to the abdominal cavity. The intestines were pale; the mesenteric glands were much swollen, and of a blood-red colour. There was a little blood-stained serum in the peritoneal sac. The mucous membrane of the intestines was covered with ecchymoses of the size of a pea and under; the solitary follicles were swollen; Peyer's patches were infiltrated. The kidneys were studded with hæmorrhages in both medullary and cortical portions; there were none in the liver or spleen. The treatment consisted in the administration of quinine and acids. Not the least remarkable point about the cases was the sudden appearance and disappearance of the eruption, more especially as the latter was unmarked by any preliminary changes of colour.

RALPH W. LEFTWICH, M.D.

LINCOLN ON AN EPITHELIAL CAST FROM THE ŒSOPHAGUS.—At a meeting of the Boston Society for Medical Observation (*Boston Medical and Surgical Journal*, October 19), Dr. Lincoln reported the case of a boy, aged nine years, who vomited an epithelial cast of the lining of the œsophagus. The boy had not been dyspeptic. On May 24 he had an

attack of catarrh of the fauces and right Eustachian tube, which subsided in a few days without doing mischief. On May 29 he was attacked by pains in the right great toe and ankle, and in the left knee, which, he said, were like those he had suffered last year in a long and severe attack of articular rheumatism. The fever was not high. Salicylic acid in three-grain pills was given every hour, and on the 31st, in the morning, having taken thirty-one of these pills, his pains had entirely left him. But at eleven A.M. he began to bleed at the nose a little; in five minutes or so he vomited a gill or two of blood, dark, with some clots, and a very little food, containing a clot seven inches long, of the size of the boy's finger, in close union with which was a cylindrical substance, reminding one of a croupy false membrane; the cylinder was complete in some parts, torn in others. The vomiting and epistaxis were easily arrested; there was no further systemic or local disturbance of any sort, and the boy recovered.

The only local complaint during the use of the salicylic acid was that of a dull feeling of pressure in the stomach.

There had been since last year a loud apex-murmur with the first beat of the heart.

Dr. Fitz described the specimen as consisting of the desquamated superficial layer of the œsophagus, the blood-clot being closely entangled with it. There was none of the papillary layer present, so that no ulcerated surface remained.

SURGERY.

WAITZ ON DORSAL DISLOCATION OF THE THUMB.—Dr. H. Waitz, of Kiel, reports in the *Berliner Klinische Wochenschrift*, no. 44, 1876, two cases of dislocation of the thumb treated by Esmarch, and advocates, as a means of favouring reduction in very obstinate forms, exposure of the joint by an incision. Through such a proceeding the surgeon may be able to discover the obstacle to reduction, and to remove it. For the success of the operation, the application of Esmarch's apparatus for rendering parts bloodless is necessary, and the dangers of exposure of the joint must be avoided by the use of Lister's spray and antiseptic dressings. The subject of the first reported case was a man aged twenty-nine years, who applied to Esmarch with a recent dorsal dislocation of the left thumb, complicated by a transverse gaping wound in front of the injured joint. Attempts to effect reduction by manipulation having failed, the thumb was rendered bloodless, and the injured parts closely examined through the wound. The tendon of the long flexor of the thumb was quite loose, and could not have prevented reduction. The capsule of the joint had been partly lacerated, and the neck of the metacarpal bone was closely surrounded by a 'button-hole' slit in this membrane. The opposite margins of this slit having been first incised and afterwards held apart by small blunt hooks, the

phalanx could at once be readily pulled to its normal position. The wound was washed out with a weak solution of carbolic acid and dressed antiseptically. Healing took place without signs of any local reaction, and on the fourteenth day the mobility and proper functions of the thumb had been restored. This case, the author states, presented two points of interest. An examination of the interior of the injured joint had led to a removal of the obstacle to reduction, which would otherwise have proved insuperable. The healing process was carried on rapidly and without reaction, and the mobility of the thumb was quite restored, in consequence, it is assumed, of the use of Lister's antiseptic dressings. A case of simple dislocation of the thumb is reported by the author, in order to show the good results of a new plan of treatment, suggested by the facts of the first case. Lucke, in a paper on dislocation of the thumb, had recommended in 1871, as a last resource when ordinary attempts at reduction had failed, incision into the joint and direct removal of the obstacle. Dr. Waitz had not met with any record of a case in which this advice had been followed, but he held that it was perfectly justifiable to have recourse to such a plan of treatment, considering that the subsequent dangers could be much reduced, or even altogether avoided, by the application of antiseptic dressings. The subject of the case in which this treatment was carried out was a man, aged seventeen years, who came to Dr. Esmarch with a simple dorsal dislocation of the right thumb, caused ten days previously by a fall. All other attempts at reduction having failed, the injured thumb was rendered bloodless, and a transverse incision made in front over the prominent head of the metacarpal bone. The capsule, as in the former case, was found to have been torn, and the neck of the metacarpal bone was closely gripped by the slit. Incision and separation of the margins of this slit did not, however, help reduction, which, after closer examination, was found to be prevented by interposition of the tendon of the long flexor muscle between the head of the metacarpal bone and the base of the first phalanx. This tendon having been raised by means of a small blunt hook, reduction was easily effected. The operation was performed whilst the injured part was under the carbolic acid spray, and Lister's dressings were subsequently applied. The wound healed rapidly, and one month after the operation the patient had good use of his right thumb.

The difficulty in effecting reduction in the first case was due to a 'button-hole' laceration of the capsule, which girt the neck of the metacarpal bone so closely that a release of this bone could not take place without an artificial enlarging of the slit. This condition is produced, according to Petersen, by the following mechanism; when the margins of the slit have arrived at the back of the head of the metacarpal bone, contraction takes place of the muscles connected with the adjacent sesamoid bones, viz., the adductor and the ulnar insertion of the short flexor on the one hand, and the abductor and the radial head of the short flexor on the other hand. The margins of the slit are thus drawn well over the head of the bone, and an almost complete interposition is brought about of the capsule between the metacarpal bone and the base of the first phalanx. This condition, by reason of the elasticity of the muscles, cannot readily be removed even on the administration of chloroform. In Dr. Esmarch's case the head of the metacarpal bone was set free

after incision into the joint, but the margins of the slit in the capsule encircled the bone so closely that it was necessary not only to cut the margins of the slit, but also to separate them further by means of blunt hooks. Reduction in the second case was hindered through interposition of the tendon of the long flexor of the thumb. This condition has been thus explained by Spitzer: the tendon of the long flexor being closely bound down to the first phalanx of the thumb, by means of tough fibrous tissue, must be carried along with this bone in any direction that it may be forced. In dislocation, the tendon, according to Spitzer, is always thus carried away; when there is but slight displacement of the phalanx, it lies alongside of the head of the metacarpal bone; when the displacement is considerable it becomes interposed between the head of the metacarpal bone and the base of the first phalanx. Waitz does not accept this view, and is disposed to think that displacement of the tendon of the long flexor in connection with dislocation of the phalanx, occurs in those cases only where the injury has been caused by a fall or blow on the inner surface of the thumb. In the former of the above reported cases, the tendon of the long flexor was seen in its normal position over the middle of the head and neck of the metacarpal bone. In conclusion, it is stated that where dorsal dislocation of the thumb cannot be reduced through ordinary means, in consequence of interposition of capsular ligament, or of the tendon of the long flexor, an incision into the joint, and direct removal of the obstruction, is preferable to any other operative treatment, provided that antiseptic dressings be used.

BECKER ON THE TREATMENT OF PSEUDARTHROSIS.—Dr. Becker, of Munich, in a communication to the *Aerztliches Intelligenz-Blatt*, no. 41, 1876, advocates as a plan of treating ununited fracture, the subcutaneous injection into the false joint of a weak solution of carbolic acid. In the treatment of pseudarthrosis, it is necessary, the author points out, to establish such a degree of inflammatory action, that the limits of plastic exudation may not be overstepped, and that suppuration may not result. The usual therapeutical measures may be divided into two classes: one class being of those which may be fairly regarded as free from danger, but which are seldom efficacious; the other of those which, though they offer a very good chance of success, often put the life of the patient in jeopardy. The dangers consist in excess of inflammatory action, as suppurative ostitis, osteomyelitis, and periostitis. Among the non-heroic plans of treatment may be classed the application of tincture of iodine, blisters, etc., to the surface of the limb at the seat of injury. The action of such irritants must be very slight in deep-seated parts and troublesome dermatitis may by these be readily produced. Acupuncture, according to the author, usually fails to set up the necessary degree of irritation. The introduction of a seton in the false joint may be regarded as an heroic measure, as it may excite profuse suppuration. Forcible rupture of the false joint and rubbing together of the ends of the fragments, may be regarded as the mildest of the heroic methods; but it may result in nothing more than annihilation of all the results of previous treatment. The cases in which this method may be tried with fair prospect of success, are those where but one bone has been fractured, where there is much displacement of the fragments, and where

the connecting bond of fibrous tissue between these bones is thick. The plans of boring the ends of the bones and introducing foreign bodies, as ivory pegs, steel screws, etc., are dangerous, on account of the probable result of suppurative ostitis. Resection of the joint, from the fact that it establishes the constitutions of a compound fracture, must be regarded as a dangerous operation.

A case is reported by Dr. Becker of a man who had received a compound oblique fracture of both bones of the left leg, at the junction of the middle and upper thirds. At the end of the third month from the date of injury, the fragments of the fibula had united, but at the seat of the fracture in the tibia there was angular distortion and much mobility, and no osseous thickening or deposit of callus had taken place at the ends of the tibial fragments. Forcible friction of the ends of the fragments having been tried, and also prolonged retention of the limb in a gypsum splint, without any good results, Dr. Becker considered how he might set up in the newly formed connective tissue of the pseudarthrosis just such a degree of irritative action that might result in plastic effusion from the ends of the fragments and consequent development of bone and firm union. As a means of directly attacking the tissues of the false joint, it occurred that the use of a Pravaz's syringe would be suitable, and as a mild irritant fluid, a weak solution of carbolic acid was selected. From the results of Hueter's researches on the injection of carbolic acid into inflamed tissues, it was assumed by Dr. Becker that this agent would produce good results when injected into bones. It destroys septic irritants, and is an unlikely agent to set up suppuration. The injured limb having been fixed in a fenestrated gypsum splint, a small quantity of a 3 per cent. solution of carbolic acid was injected between the ends of the fragments of the broken tibia. As no evident result had been produced by this proceeding, a 4 per cent. solution was subsequently injected. This caused no local pain or constitutional disturbance, but set up some inflammatory cedema in the soft parts over the false-joint. During the following sixteen days the injections were repeated on four occasions, and on the seventeenth day periosteal thickening could be distinctly felt at the end of the lower fragment. One week later the gypsum splint was removed, and then it was found that the fragments were firmly united. Eight days later there was an abundant deposit of callus on both the anterior and posterior surfaces of the tibia, and at the end of another month there was firm osseous union, and the patient could walk well with the support of a stick.

DOLLMAYR ON RETENTION OF URINE IN FEMALES.—Dr. Dollmayr, of Vienna, directs attention, in the *Medicinischo-Chirurgisches Centralblatt*, no. 40, 1876, to what he believes to be a frequent though seldom recognised cause of retention of urine in females. The form of retention to which the author alluded is only met with, he states, in subjects of advanced age and in those who have long ceased to menstruate. The first indication of the urinary disturbance is a burning sensation at the external meatus during micturition, slight at first, but gradually extending and increasing in intensity, so that the patient soon, whilst passing urine, feels as if a red-hot needle were lodged in the whole course of the urethra. The stream of urine becomes smaller, and at last there is much difficulty in re-

lieving the bladder. If, in an extreme case of this kind a close examination be made of the external urethral orifice, this will be found blocked up by small ruddy excrescences which bleed freely when touched. This condition the author is disposed to attribute to continued inflammatory action set up in the mucous membrane of the urethra by some local cause, the result of such action being polypoid thickening of the membrane. The excrescences may be speedily destroyed by the application of nitrate of silver or sulphate of copper, and then the urethral pains and the difficulty in micturition will at once disappear. In conclusion, the author insists on the necessity, in cases of retention of urine in the female, of submitting the urethra to close examination.

KÜPPER ON HÆMORRHAGE AFTER THE APPLICATION OF ESMARCH'S METHOD.—Dr. Küpper, of Elberfeld, points out (*Deutsche Medicinische Wochenschrift*, no. 43, 1876) that Esmarch's plan of arresting hæmorrhage during surgical operation is attended with one serious disadvantage. When the large vessels have been tied, and the elastic ligature has been removed, there is usually free and prolonged bleeding from many small branches, so that the surgeon is often compelled to tie twice or thrice the number of vessels that he need have tied had Esmarch's apparatus not been used. When the antiseptic spray and dressings are used, this bleeding is especially disadvantageous. The application of Esmarch's apparatus to a limb is followed, as is well known, after removal of the elastic ligature, by intense redness of the skin, and by increase of temperature in parts below the seat of compression. From the analogy of these phenomena to those presented by the external ear of an animal after division of the cervical portion of the sympathetic, the author has been led to the conclusion that the application of Esmarch's apparatus causes paralysis of the arterial muscular tissue, either by direct action on this tissue or by indirect action on its nerves. The less the contraction of the muscle, the greater remains the lumen of the vessel, so that a thrombus is not so readily formed. Cold arrests hæmorrhage, because it excites vigorous contraction of the muscle, whilst warmth by relaxing this tissue favours loss of blood. The author proposes, as a means of preventing hæmorrhage due to paralysis of arterial muscular tissue, the application of a strong induced current, one pole being placed at some distance from the seat of operation, the other on the surface of the wound, and in direct contact with the divided vessels and nerves. A case is reported, in which this proceeding was practised with the expected result.

CRUSSARD ON INGUINAL ADENITIS SIMULATING STRANGULATED FEMORAL HERNIA.—Dr. Crussard, of Neufchâteau, reports in the *Revue Médicale de l'Est*, no. 5, 1876, a case of acute inguinal adenitis, complicated by symptoms of intestinal strangulation. That difficulty might occur in distinguishing between an inflamed inguinal gland and a strangulated hernia was recognised by Boyer and Nélaton, who, allowing that constipation and vomiting were very rare symptoms in association with adenitis, took care to point out that, when these complications were present, certainty in diagnosis often became impossible. The author has brought forward his case for the purpose of throwing some light upon this difficult point in practical surgery.

The question discussed by the author in some remarks on his case is thus stated: 'There being given a tumour in the fold of the groin, which has existed for several days, presents all the signs of an inflamed femoral hernia, and is accompanied by the characteristic symptoms of strangulation—the subject of this tumour having long suffered from hernia in the same region—to determine whether the tumour be a strangulated hernia or simply an inflamed gland.' In considering this important question, the surgeon may be best guided by his previous knowledge of the tumour or, failing this, by the patient's own report as to its previous form, size, and consistency. In the absence of any report as to the former condition of the swelling, the diagnostic difficulty will, the author thinks, always remain very great. This communication contains the following general conclusions. 1. Inguinal adenitis may, in certain instances, simulate strangulated femoral hernia. 2. The diagnosis is simple if the patient have a recent hernia, and be seen in good time; unnecessary if the surgeon be not called in before the development of manifest fluctuation which demands the same operation; of great importance and attended with much difficulty if the patient has long been ruptured in this region, and the surgeon be not called in until a period when the nature of the tumour can no longer be made out on examination. 3. In a case of this kind, some knowledge as to the former condition of the region affected will be of great service to the surgeon; this alone may excite his suspicions, and even enable him to form a certain diagnosis. 4. There are cases, however, in which little or no information can be obtained, and here the surgeon would conceive no suspicion were he not aware of the possibility of error. 5. In the presence of these sources of doubt, it is to treatment that one must have recourse, in order to attain certainty; it is thus one may learn the true nature of the symptoms. A free application of leeches will rapidly put an end to the sympathetic symptoms set up by an inflammation, and which simulate strangulation. In case of true strangulation this plan would not be disadvantageous. In any case, it need not lead the surgeon to delay too long in having recourse to an operation, should the strangulation persist or increase in severity.

W. JOHNSON SMITH.

NOTTA ON NEUROMA OF THE MEDIAN NERVE: EXCISION AND SUTURE OF NERVE.—At the meeting of the Surgical Society of Paris, on November 8, M. Notta brought forward this case. A tumour of the size of a hazel-nut existed on the anterior surface of the forearm, presenting all the objective and subjective symptoms of a neuroma of the median nerve. This was excised, and the ends of the nerve (retracted about three centimètres) were brought into contact by a metallic suture. After the operation, anæsthesia was proved to exist in the parts supplied by the median nerve. Formication was soon felt. On the thirteenth day sensibility reappeared in the ring finger; on the sixteenth on the thenar eminence; elsewhere the return was more gradual; eight months after the operation, the patient could feel as well with one hand as with the other. At the same time, peripheral ulcerations on the index and middle finger had healed. Microscopic examination showed that the tumour was a fibro-sarcoma in the substance of the median nerve, with the nerve-fibres separated and stretched over it. M. Verneuil said that in his opinion to employ sutures to obtain reunion of nerves

was useless, and founded on a wrong principle. In such cases, sensibility always returned from the periphery towards the centre, and was due to collateral innervation, and not to the reformation of the nerve and the passage of nervous impressions along newly formed nerve-fibres. Sufficient time had not elapsed for this to have taken place in M. Notta's case, where sensibility began to return on the thirteenth day. So, too, in excision of the lower jaw, where the inferior maxillary nerve was destroyed, sensibility began to return the day after the operation, and first in the middle line. He would quote the case of a young lady brought to him with the fingers of one hand extremely flexed upon the palm, the superficial flexor tendons and the median nerve being embedded in a cicatrix resulting from ulceration due to the faulty application of a splint. The fingers were movable and sensitive. In the course of an operation, which was attempted to isolate the flexor tendons, the median nerve was cut across. After the operation, however, sensibility was in no way affected, its preservation being obviously due to the collateral innervation of the parts. [If reference be made to an article on this subject by the translator in the *British Medical Journal*, April 1, 1876, the following explanation by Dr. Richet of 'collateral innervation' will be found. The terminal filaments of the radial, median, and ulnar anastomose amongst themselves to form loops, from which come off the filaments which end in the touch-corpuscles. As both loops and filaments are compound, containing filaments from the median, radial, and ulnar, section of one of these trunks is powerless to deprive of sensibility the corpuscles which are the essential organs of touch.—*Rep.*]

W. H. A. JACOBSON.

SCHRÖTTER'S METHOD OF ANÆSTHESIA OF THE LARYNX BEFORE OPERATION.—In the treatment of diseases of the larynx, some patients are met with in whom sensitiveness is so excessive that it is beyond the ability and patience of the most perfect operator. It is also not uncommon to be so pressed for time that the series of proceedings necessary to bring the patient to complete tolerance cannot be gone through. It is for these special cases that laryngeal anæsthesia, invented by Turck and perfected by his pupils, especially by Schrötter as described in the *Progrès Médical*, October 14, 1876, should be reserved. The latter performs it at the Vienna Hospital in the following way. If the operation is to be performed the next day, at about seven o'clock on the preceding evening the laryngeal mucous membrane is touched twelve times in succession with a pencil steeped in pure chloroform. This proceeding is intended to bring on intense congestion of the mucous membrane, and to place it in the most favourable condition for absorption. At eight o'clock, that is to say, one hour afterwards, a pencil steeped in a saturated solution of acetate of morphia, is plunged twelve times in succession into the larynx. The patient must take care not to swallow, and between each painting should rinse the mouth and throat, as an antidote, with a gargle composed of 10 parts of tannin and 15 of alcohol, in 200 of distilled water. It is advisable to visit the patient about midnight, to make sure that no marked symptoms of poisoning by morphia exists. At seven o'clock in the morning, the larynx is generally found to be insensible and it can be operated on. If a small amount of sensitiveness still exist, the paintings are renewed twelve times, and so on every hour

until the object sought is attained. The disadvantages of this method are the fear of poisoning by morphia, easily removed by a little watchfulness and by the recognised remedies. The advantages have been already enumerated, and indeed it is necessary to have been present at one of these operations, rendered so easy in a patient who the evening before was considered to be entirely unamenable to treatment, to appreciate anæsthesia of the larynx at its just value.

STANFORD ON REMOVAL OF A PLATE OF PEWTER FROM THE OESOPHAGUS.—Dr. F. A. Stanford, of Columbus, relates in the *New York Medical Journal* for October, the case of Joel Turner, aged about fourteen, who swallowed a piece of pewter on February 19, 1876. Dr. C. D. Hurt, of Hurtville, Alabama, was immediately called upon, and after exhausting many ingenious expedients without avail, accompanied the boy to the city for Dr. Stanford's assistance.

The next morning, his appearance indicated very little distress, but his anxiety for relief was great. His breathing was not interrupted. Dr. Stanford passed the umbrella probang without difficulty downward, about seven inches, when it came into contact with the foreign body. Having cautiously continued the probang downward into the stomach, he expanded the bristles to the full umbrella size and began to withdraw. The probang, however, when withdrawn, left the body still in the throat. Dr. Stanford immediately selected four ligatures of surgeon's silk, which he tied to the distal extremity of the probang, and then passed each separately through the extreme outer margin of the bristles, expanded to full umbrella size, brought them upward, and tied them fast to the spool slide.

He again passed the probang beyond the plate, expanded the umbrella, and, drawing hard upon the four ligatures at the same time, made a complete revolution of the probang, hoping by that means to surround the pewter plate, and bring it within at least one or more of the ligatures. Everything being ready, his assistants each held two of the ligatures throughout the process of withdrawal. The ligatures being kept fully tight, the plate was soon withdrawn.

The pewter plate was one inch and three-eighths in diameter, one-fourth of an inch in thickness, and weighed one ounce and one-fourth; it was circular in form.

UHLER ON THE CHEMICAL DETECTION OF LEAD AND IRON BULLETS IN GUNSHOT WOUNDS.—Dr. J. R. Uhler has communicated to the Maryland Academy of Sciences (*American Journal of Medical Science*, October) a method for the more certain detection of leaden and iron bullets when imbedded in the tissues, as in gunshot and shell injuries, especially where they have taken an obscure or curved course, and cannot be readily felt by finger or probe.

The plan was suggested in 1863 by noticing a case in hospital where sulphuretted hydrogen from pus had blackened ordinary lead plaster, and after a little thought was tried and perfected on the spot. It consists of employing materials capable of dissolving lead or iron, such as very dilute nitric acid, and then testing the solution by the usual plan for those metals.

The apparatus consists of a syringe to thoroughly cleanse the wounds with pure water, after which a

solution of nitric acid, five to fifteen drops to a drachm of distilled water, is injected into the wound and allowed to remain a short time, to come into contact with and dissolve a portion of the ball. The injected fluid is then withdrawn either by syringe, or by changing the position of the patient so as to let it run out, and is received when possible at two places, upon a white porcelain plate. One of these spots is now to be tested by a small crystal or drop of solution of iodide of potassium, which will produce a golden-yellow colour if lead be present. The other may be treated by a solution of sulphocyanide of potassium, giving a beautiful red, or ferrocyanide of potassium, affording blue if iron be there. Both of these methods are extremely delicate, and can only be obscured by neglect to wash away pus with accompanying chloride of sodium, or inexcusable carelessness causing loss of blood, and thus producing the reactions of iron from the small quantity contained in the blood-corpuscles. To show most efficiently, the fluid on the plate ought to be colourless, or but slightly tinged like serum. The syringe should generally be introduced but a short distance into the wound, so as to give rise to as little irritation as possible, and the nitric acid solution for the same reason be very dilute. The whole procedure is less irritant than probing, and also extremely useful to the patient, as dilute nitric acid has long been esteemed one of the best dressings for hospital sores.

CRAWFORD ON A CASE OF DISLOCATION OF BOTH HIPS.—Dr. J. B. Crawford (*American Journal of the Medical Sciences* October, 1876), was called on July 13 to see Thomas Jones, a large and powerful man, aged about thirty, who had been injured four or five hours previously while working in a coal-mine, by a mass of rock from the roof falling upon him. Upon examination, a dislocation of both hips was found; the head of the right femur rested upon the dorsum of the ilium, the leg was flexed upon the thigh, the knee lay upon the lower portion of the opposite femur, and the toes were turned strongly inwards. The head of the left femur was displaced into the ischiatic notch. The limb was nearly straight, the thigh being but slightly flexed, the knee nearly unbent, and the toes inverted. The lower portion of the spine was strongly arched. The amount of shortening could not be ascertained. The amount of deformity of the hips was less conspicuous than is usual in single dislocations of the same kind.

The patient was thoroughly anæsthetised, and the reduction effected by manipulation. First flexing the left leg upon the thigh and the thigh upon the pelvis, Dr. Crawford pressed the thigh obliquely across the abdomen, at the same time rotating the femur, using the leg as a lever, and then carrying the knee across to the left side, lifted the thigh to a right angle with the body, and made moderate vertical traction; when, after dislodging the head of the bone from the sciatic notch, it glided readily and noiselessly into its proper place. Considerable force, with rotation of the femur, was required to carry the flexed thigh across from the right to the left side of the abdomen; all the other movements were effected with comparative ease. Not more than two minutes were occupied in the process. The reduction of the remaining luxation was attended with more difficulty. Dr. Crawford first moved the limb in the line of its easiest motion; flexing the leg upon the thigh, and the thigh upon the pelvis, as before, carrying the knee well upward and obliquely across the median

line of the body. Then attempting to abduct while rotating the limb, he found the movement in that direction suddenly arrested. Again, pressing the thigh firmly upon and obliquely across the abdomen, and abducting and rotating as before, he succeeded in disengaging the head of the bone and bringing it apparently to the posterior border of the acetabulum; but upon bringing the limb down to a horizontal position, the head of the femur had returned to its former situation upon the dorsum ilii. The manipulations, varied somewhat, were repeated several times with the same result. Finally, having brought the head of the femur to the posterior border of the acetabulum, and finding it again arrested at the edge of the socket, Dr. Crawford directed the pelvis to be held firmly down by two assistants while he made strong upward traction upon the thigh bent at a right angle with the body. In about a quarter of a minute, the dislocated bone returned to its socket with a sound that was heard distinctly. The patient left his bed ten days after the reception of his injury, and walked about the ward with but slight difficulty.

The records of surgery furnish but a very few examples of simultaneous dislocation of both hips. Dr. Gross, in his 'System of Surgery,' says that the accident is exceedingly uncommon, and mentions but three instances of its occurrence—one recorded by Professor Gibson, one by Cooper, of London, and one which occurred in the practice of Dr. Boissot, of Philadelphia. Hamilton, in his work on 'Fractures and Dislocations,' mentions only a single example of this injury, that of Professor Gibson. Each of these cases, where the particulars are given, differed from the others, as well as from the one here recorded, in regard to the character of the dislocation; in one the displacement being iliac and thyroid, in the other iliac and pubic, while the one here recorded was iliac and sciatic.

The subject of the present report informed Dr. Crawford that he was at work, standing on a surface which inclined at an angle of about forty degrees, with the feet widely separated, the right one being much lower than the left, and the body bent forward. While he was in this position, a large mass of rock, weighing many hundred pounds, fell from the roof, several feet above him, striking him in the lower dorsal region, bending the thighs upon the body and pressing him forcibly down upon the rock on which he was standing. He was certain that both joints were dislocated at the same instant, as the falling rock immediately rolled or slid from and released him. Severe bruises upon his back, and a deep cut on the right arm, were the only other injuries received.

DISLOCATION OF THE MALAR BONE.—The *New York Medical Journal* for October states that a case of dislocation of the malar bone was then under observation in St. Francis's Hospital. The dislocation was caused by direct injury, resulting from a fall, and was compound. The wound was external to the outer canthus of the eye, and it would seem that some projecting body, striking the patient in his descent, was the immediate cause of the injury. On passing the finger into the mouth, it was noticed that the lower angle of the bone rested on the outer side of the molar teeth. By making pressure it could be apparently replaced, but so far no attempt at reduction had been considered advisable.

BUNDY ON FIBRO-MUSCULAR TUMOUR OF THE PROSTATE.—Dr. Bundy, at a meeting of the Boston Society for Medical Observation (*Boston Medical and Surgical Journal*, October 19), showed a specimen of fibro-muscular tumour of the middle lobe of the prostate. The patient was seventy-seven years of age, and fifteen years ago was told that he had an enlarged prostate. During the past three years his urine had at times contained blood. Ten weeks before death he began to be troubled with frequent desire to pass water, attended with pain and dribbling of urine. Dr. Bundy saw the patient five weeks ago for the first time, when he drew off two quarts and a half of urine. The patient then stated that he had noticed his bladder to be abnormally distended for some weeks before. At first the catheter was required only twice or three times a day, but during the last week of life as often as every four hours.

During the last few days of life only there was much trouble in passing the catheter. The tumour was so attached to the bladder by a short, thick pedicle, as to act as a partial valve to the urethra.

MATERIA MEDICA AND THERAPEUTICS.

BURRALL ON NITRITE OF AMYL AS AN ANTIDOTE TO CHLOROFORM.—At a meeting of the New York Academy of Medicine, on September 21, Dr. F. A. Burrall read a paper on nitrite of amyl as an antidote to chloroform, in which he brought it forward as the most available of all medical agents to avert the dangerous influence of chloroform when used as an anæsthetic. It was believed that nitrite of amyl acted as an antidote to chloroform by producing a direct paralysis of the vascular walls, hence causing a rapid circulation. Dr. Burrall recapitulated the experiments performed upon cats and dogs by others and himself, and said that amyl should always be in the armamentarium of the medical man. It could be administered from a bottle, or five or six drops might be placed on a handkerchief

and held to the nose and mouth of the patient. An exceedingly convenient method of carrying the drug was by means of the nitrite of amyl-bulbs suggested by Dr. T. A. McBride. When required, one of the bulbs could be broken in a handkerchief or towel, and its contents immediately inhaled.

Dr. G. M. Smith remarked that the question might arise whether the antidote was not a dangerous agent.

Dr. S. Caro said that one of his patients, who suffered from angina pectoris and was treated by the nitrite of amyl in drop-doses taken by the mouth, fell into a sort of collapse after the fifth dose, which he was quite certain would have proved fatal had not the influence of the drug been arrested by a vigorous administration of aromatic spirits of ammonia.

Dr. J. C. Peters was inclined to attribute the collapse in Dr. Caro's case to the prostrating effect produced by the angina.

BLAKE AND OTHERS ON THE TREATMENT OF GASTRIC ULCER.—In a paper read by Dr. J. G. Blake before the Boston Society for Medical Observation, and published in *The Boston Medical and Surgical Journal*, October 19, he says that the most successful treatment of gastric ulcer is rest, meanwhile supporting the system by nourishment introduced through other channels. Fortunately, the large intestine allows this to be done, and for sufficiently long periods, when care is exercised in the selection and preparation of articles of nourishment. In addition to the ordinary substances used, as beef-tea or juice, strained oatmeal gruel, and white of egg, attention has, within a few years, been called to the value of minced fresh meat, thoroughly incorporated with the pancreas of freshly killed pigs in the proportion of two parts of the former to one of the latter. In a case of intestinal obstruction under observation, recourse was had to this among other methods of sustaining the strength without loading the bowels above the obstruction. The method of proceeding was to have a messenger waiting at a slaughtering establishment, who received the pancreas and brought it without delay to the patient's residence. Here the physician, after removing the fat and selecting the true glandular substance, mixed it thoroughly with the finely divided meat, and placed it, in the form of a soft sausage, as high in the rectum as was possible without inflicting pain. The result was highly satisfactory for a time. In from six to twelve hours the parts not absorbed came away in the form of a thick, creamy emulsion. The patient declared that he felt stronger, and derived more benefit from this than from an injection of beef-juice. After repeating it ten or twelve times, however, the intestine became sensitive and painful, and it was necessary to discontinue it. The chief objection lies in the difficulty of complying with all the conditions. The pancreas must be fresh; if more than two hours from the living animal, its value is much impaired or lost. The pig should be killed after a full meal. It is also desirable to get the mass high up in the colon, and this is by no means easy of accomplishment.

Dr. H. I. Bowditch remarked that in cases in his own practice he had found soft, stale bread in milk to be retained when nothing else would. If constipation resulted, it might be corrected by the use of bismuth and rhubarb. He usually began with a very small quantity of milk, not more than a teaspoonful,

and gradually increased it. Often the slightest deviation from this form of nourishment would cause the vomiting to return. He thought this treatment should be continued for a long time. One patient under his care had lived on this diet almost exclusively for weeks.

Dr. Hildreth referred to the solvent action of fresh pancreas in the digestion of beef-tea. In two cases of gastric ulcer, in each of which enemata of beef-tea with fresh pancreas had been given, the discharges were of a yellowish colour. Dr. Hildreth thought the injection might be more effectually given by attaching to the syringe a glass stem connected with a moderately long India-rubber tube. He had treated a lady with beef-tea enemata, who had previously had the same with fresh pancreas added to it, and she had noticed no difference whatever in the effects produced.

PSYCHOLOGY.

DUKES ON A SIMPLE MODE OF FEEDING SOME PATIENTS BY THE NOSE.—Mr. Clement Dukes (*Lancet*, Sept. 16, 1876) describes a method of nasal feeding, which might probably be of great service in the private practice of insanity.

The apparatus consists of (1) a yard of India-rubber tubing of one eighth of an inch bore; (2) a bottle of any kind (an ordinary soda-water bottle does well); (3) a piece of twine to tie the tube in the bottle, so that the end of the tube reaches to the bottom of the bottle.

The mode of action of this apparatus is that of a syphon. 1. The bottle with the fluid in it is held or fastened above the head of the bed; the patient lying on his back, without a pillow. 2. The tube is exhausted of air, by laying hold of the tube close to the mouth of the bottle with the finger and thumb of the left hand, and running the finger and thumb of the right hand along it, closely compressing it while doing so; the fluid of course following the motion of the hand, when the pressure of the left hand is removed. 3. The free end of the tube is then passed just within the nostril, and retained there with the left hand, while the right has the tube closed by the pressure of the finger and thumb. 4. By alternate compression and relaxation of the tube an ordinary mouthful of fluid can be allowed to escape at a time, permitting each quantity, if desired, to pass into the stomach before another gulp is liberated. This syphon can also be used for washing out the nose, the patient's head being inclined forwards over a basin.

[It is presumed that the above described nasal-tube could be passed down the nostril into the œsophagus, if necessary.—*Rep.*]

H. SUTHERLAND, M.D.

OBSTETRICS AND GYNÆCOLOGY.

VAN DE WARKER ON THE TREATMENT OF ANTE-FLEXIONS OF THE UTERUS.—Dr. Ely Van de Warker, of Syracuse, N.Y., describes a new ante-flexion pessary which he has designed from that of Dr. Eklund. The principle on which it is constructed is that the instrument should be so made as to bring the posterior vaginal wall into play as the point of counter-pressure to the force of anterior displacement. This is effected by means of a stem, which fits into a flange, which presses against the posterior vaginal wall; the flange is a flat oval in form, bent at right angles. Dr. Van de Warker has the flange made in different sizes to suit different cases. Success depends upon the flange being accurately fitted.

DEPAUL ON RETENTION OF A DEAD FŒTUS.—In his 'Clinique d'Accouchements' (*Journal des Sages-Femmes*, September 16, 1876), Professor Depaul gives the case of a child born dead at term. The child was macerated, but bore no traces of putrefaction. The patient had carried the dead child twenty, and perhaps thirty days or more, without any accident. M. Depaul remarks that when a child is dead in the uterus, so long as the membranes are intact the labour need not be excited, and one must not confound, as has often been done, maceration with putrefaction.

CHAMBAUD ON OBLITERATION OF THE OS UTERI IN A PREGNANT WOMAN.—Dr. Chamberaud gives (*Archives de Tocologie*, September, 1876) an account of a case of complete obliteration of the uterine mouth in a pregnant multiparous woman. The case began as follows. On March 2, 1875, Dr. Chamberaud was called to the patient, a young healthy woman, aged twenty-six. She was in bed, sweating profusely; respiration short and hurried; pulse regular, 130 per minute. She was in great pain in the loins; the abdomen was hard, tense, and tender; the uterus was enlarged; and apparently there was a pregnancy of two months. Dr. Chamberaud ordered fifteen leeches to be applied to the right iliac region, with warm poultices to assist the flow of blood. As the bowels were confined, an injection of oil was ordered. A few days afterwards, the patient was much better. On March 14 Dr. Chamberaud was called again to her, as there was a purulent discharge from the vagina. On examination by the speculum, Dr. Chamberaud found considerable ulceration of the os, with a discharge of thick purulent matter like white of egg. He at once applied nitrate of silver, and repeated this application once a week till June 13 following; that is, he made fourteen cauterisations. He did not see her again till June 27, when he found the os uteri completely closed by a cicatricial tissue joining together the lips. He then called in Dr. Bessette, who also examined the patient, and found the obliteration of the os complete. Having thus become quite clear as to the diagnosis, Dr. Chamberaud wrote to ask Professor Depaul how he should treat the case, and was advised by him to leave it till term, when, if the uterine efforts were insufficient to break

down the cicatricial tissue, the division thereof by a bistoury would be necessary.

On August 15, at half-past three in the morning, Dr. Chambaud was called to the patient, when he learnt that she had been in labour fourteen hours. After waiting three hours to see if some instruments he wanted had arrived, Dr. Chambaud proceeded to make an incision through the closed os. The incision made was only large enough to admit the extremity of a finger, and in making it the bag of waters was pierced, and liquor amnii escaped. Dr. Chambaud then broke down the remaining tissue with his finger, and the head coming down filled up the opening completely. At half-past twelve a non-viable female child was born, which died the next day. The patient had a high temperature and frequent pulse for a few days, at the end of which she made a good recovery.

Dr. Chambaud is convinced that if he had seen the patient the day after he found her out instead of waiting a fortnight, he would not have had the task of communicating this curious and interesting case.

SIMON ON OPERATION FOR VESICO-VAGINAL FISTULA.—Dr. Simon, of Heidelberg, (*Obstetrical Journal of Great Britain and Ireland*), in a paper on the method of operating for vesico-vaginal fistula, compares his own operation with that of Bozeman, of New York. Simon operates in lithotomy position, draws the parts round the fistula forwards, pares the edges with a knife, uses a simple knotted silk suture, enjoins no measures of precaution as regards passing urine after the operation, and allows the patient, if she please, to leave her bed on the second or third day after the operation. Bozeman operates in the knee-elbow position, leaves the fistula *in situ* while operating, pares the edges with scissors, employs a complicated wire suture, leaves a catheter in place after the operation, and often gives large doses of opium. Dr. Simon gives seven cases, four by himself and three by Bozeman, who operated when on a visit to Heidelberg. From the results of these cases, Dr. Simon considers his method superior to Bozeman's.

MARDUEL ON UTERINE THERMOMETRY AS A MEANS OF DIAGNOSING PREGNANCY AND DEATH OF THE FÆTUS.—In the *Lyon Medical*, October 29, 1876, Dr. P. Marduel gives the results of the experiments in uterine thermometry by Cohnstein, Fehling, Schlesinger, and Alexieff. They are as follows. In a gravid uterus containing a living child, the temperature is from 0.27° to 0.54° Fahr. higher than in the vagina, the temperature in the vagina being higher than in the axilla. In a gravid uterus containing a dead child, the temperature is lower than that of the vagina.

The uterine temperature is also raised in inflammations of the organ, as perimetritis, endometritis, etc. Alexieff has, during labour, taken the buccal and rectal temperatures of the fœtus, and has found them to vary from 1.26° to 2.34° Fahr. for the rectal temperature, and from 0.54° to 1.26° Fahr. for the buccal temperature, above that of the vagina.

GALABIN ON THE ACTION OF MIDWIFERY FORCEPS AS A LEVER.—In the *Obstetrical Journal for Great Britain and Ireland*, October, 1876, Dr. Galabin remarks that the oscillatory movement is superfluous in all cases where extraction can be effected by forceps with moderate force, and it is useless when the head is movable, friction taking

little part in its retardation. When the head is impacted, a very slight oscillation, in which the head is made to take part, may assist in starting it by converting the greater statical into the lesser dynamical friction. When the head is impacted, and great force is required for its extraction, a mechanical advantage may be gained from leverage by having recourse to oscillatory movement. The oscillations should be of very small amplitude, and should only be continued if it be found that each of them causes a corresponding advance of the head. Each oscillation should be accompanied by firm compression of the head to prevent the forceps from slipping and the lever from becoming decomposed. Dr. Galabin does not think that the oscillatory movement, when the head is high in the pelvis, can be justified.

FANCOURT BARNES, M.B.

TRENHOLME ON REMOVAL OF OVARIES.—Dr. E. H. Trenholme relates (*Obstetrical Journal of Great Britain and Ireland*) two cases of ovariectomy, or spaying. In the first case he removed both ovaries through an incision in the abdominal wall, between the umbilicus and pubes, five inches long. His reason for doing so was the presence of an interstitial fibroid in the uterus, which was wearing out the patient by pain and hæmorrhage. His theory was, that by the removal of the ovaries the patient would be made forty-five instead of thirty-two, and that the tumour would disappear in the way these tumours often do at the change of life. The patient recovered perfectly, and is in good health. In the second case he removed the left ovary from a woman twenty-eight years old, suffering from dyspareunia and chronic oöphoritis, with the result only of relieving the dyspareunia. The ovary was removed through an incision in the posterior wall of the vagina.

RABORG ON INDUCTION OF PREMATURE LABOUR BY AN INTERRUPTED CURRENT OF WATER.—At the meeting of the Medical Society of the County of New York on September 25 (*New York Medical Journal*, November), Dr. S. A. Raborg, after reviewing the different conditions in which premature labour was indicated, drew special attention to three cases which had come under his observation, and in which labour had been induced by a current of water carried against the cervix. The first patient was twenty-five years of age. Before coming under the observation of Dr. Raborg, she had several abortions and labours, in which delivery was accomplished by means of version and craniotomy. Her pelvis measured two and a half inches in the antero-posterior diameter, and about the same length in the transverse and oblique. After consultation, it was deemed expedient to bring on labour at the eighth month. For this purpose, an interrupted current of water was carried against the posterior wall of the cervix by means of a Davidson's syringe. Within twenty-four hours pains were induced, and at the end of five days and twelve hours the mother was delivered of a child without the aid of mechanical interference. In a succeeding pregnancy the continuous current of water was employed by means of an elevated reservoir. Labour was accomplished in nine days and twenty-three hours.

In another case the intermittent current was again employed, and after five days and eleven hours labour was completed. In reviewing the two cases, Dr. Raborg said that he felt that the current of water

from the syringe was more satisfactory than the continuous current.

Reference was made to the method suggested by Dr. T. G. Thomas, in which the nozzle of a Davidson's syringe was introduced within the cervix uteri, and, after compressing the cervix, the current of water was carried against the membranes in such a manner as to partly detach them. By Dr. Thomas's method, labour has frequently been finished within twenty-four hours.

Dr. Isaac E. Taylor did not approve of the vaginal injection of water, inasmuch as he had noticed that not only was it unreliable, but in some cases seemed even to retard labour. In bringing on labour, he relied on the use of Barnes's dilators as the most efficient means of expanding the cervix uteri.

DERMATOLOGY.

ZUNKER ON TWO CASES OF VASO-MOTOR NEUROSIS.—The first case (*Berliner Klinische Wochenschrift*, August 21 and 28) was that of a robust man, aged twenty, who presented himself, at the Clinic, for nettlerash. He had had a rather obstinate attack of the same kind two years before, but had otherwise been quite healthy. The present eruption appeared on May 26. It commenced on the arms and chest, and soon spread to every part but the face, though the aspect of this was so peculiar as to at once attract attention. The chin and both cheeks, temples, and ears, were deep red, shining, and tense, though without any circumscribed hardness. The temperature of the parts was apparently not increased; the pupils were equal, both enormously dilated; reaction to light was good. On the chest and abdomen were moderately large isolated or confluent patches, of reddish colour and irregular form; they were associated with resistant, sharply defined, pale-red elevations. On pressure with the finger-nail or with a sharp instrument, they could be produced with absolute certainty. The sensations felt during their artificial production consisted in itching, and a transient feeling of warmth. No source of reflex irritation could be discovered; the organs of digestion, circulation, and respiration appeared perfectly normal. Strychnine and atropia were successively tried, in combination with tepid baths, but without effect; and it was not till June 12, when 13 lbs. of sea-salt were added to the bath daily, that the symptoms began to subside. No fresh spots showed themselves; the redness and turgescence of the face disappeared, and the pupils

became of the normal size. On June 19 he was discharged at his own request, having then no subjective troubles. The patient was made the subject of many experiments. The following were the changes produced by simple mechanical irritation with a blunt instrument. First, a transient paleness, common to all skins, appeared; then cutis anserina developed itself, not only in the irritated stripe itself, but for a varying distance beyond it. At the end of thirty seconds a slight, though distinct redness appeared in the centre of the stripe, and, a few seconds later, the skin bordering upon it became paler, while the redness increased until it corresponded exactly with the breadth of the instrument and the course taken by it. As the redness deepened, the pale zone grew more marked, and sent out, here and there, processes which were bordered in turn by a third zone of pale red colour. At the end of two minutes, by which time the third zone was complete, the skin of the central red stripe became elevated, especially around the hair-follicles. This elevation extended itself first to the entire irritated surface, and then crossed over into the pale zone, of which it occupied about two-thirds. At the same time the outer red zone began to grow inwards, so that, in four or five minutes, a white, sharply defined, very elevated wheal, upon a vividly red ground, presented itself. The raised surface was flat throughout; the prominences of the papillæ and hair-follicles having disappeared. In from fifteen to twenty minutes the redness began to fade, the wheal became smaller, and finally disappeared, leaving, as the only trace of its existence, a palish, slightly elevated semi-resistant spot, which lasted in one instance about eight hours. Experiments were next made to ascertain whether other modes of irritation would produce the same results. Heat, cold, nitric acid, acetic acid, faradisation, galvanism, all failed, though the patient seemed very irritable to the last of these. The development of a wheal could be arrested by means of ether-spray; and mechanical irritation failed to produce them on a surface made anæsthetic by this, though the susceptibility to their production returned with the resumption of sensation. When irritation was applied to a limb rendered bloodless by Esmarch's bandage, no change was produced until the elastic tube was removed, when the wheals appeared as usual. Similar, though not quite such complete results were obtained by digital compression of the main artery of the limb; a red stripe appeared, which afterwards became bluish, and on the removal of the pressure, provided this were early, the wheal showed itself. The results obtained by compression of the veins were the same as those described by Auspitz.

The second patient, also aged twenty, was a worker in white lead, and was in the hospital for lead-colic. Wheals, similar to those of the other patient, could also be produced in him; the paleness, however, was much more fugitive, and the elevation was somewhat less marked. Their production seemed to depend upon the presence of lead in the system; for, as the symptom of poisoning diminished, the difficulty of eliciting them increased, and, some days before the skin had recovered its normal sensibility, the experiment failed altogether. The same attempts were made as in the other case to produce them by irritation other than mechanical; and with similar results. The only exception was that, when Esmarch's bandage was used, the wheals did not show themselves on the removal of the ligature. Indeed, irritation soon after its removal failed to pro-

duce any effect. The wheals were believed to consist in a serous infiltration of the rete mucosum and the superficial layer of the corium; and not, as in Gull's cases, in a contraction of the muscular fibres of the skin. The pale zone was referred to a direct peripheral contraction of the vessels, and not to reflex action; the outer red zone, on the other hand, was attributed to a reflex dilatation of the vessels; the increased irritability lying in the vaso-motor nerves, and not in those of sensation. The central area of redness was explained by the dilatation of the arterioles consequent partly upon mechanical irritation, partly upon a congestion compensatory to the surrounding anæmia. Further, since the capillaries and venules were not at first correspondingly dilated, an obstruction to the flow of blood ensued, which resulted in the transudation of the liquor sanguinis. The quantity of this, if great, would cause the elevation to transcend the limits of the irritated surface. Reasons, derived in part from observation of these cases, in part from the physiological and pathological experiments of others, are given for these conclusions.

NEUMANN ON GALVANO-CAUSTIC IN SKIN-DISEASES.—Neumann (*Allgem. Wiener Mediz. Zeitung*, no. 28, 1876) describes a galvano-caustic apparatus made for him by Leiter, of Vienna, which he recommends especially for the destruction of isolated lupus-nodules. The advantages of the apparatus consist in facilities for fixing the part, and limiting accurately the depth of the tissue which is to be destroyed.

NEUMANN ON THE TREATMENT OF ACNE ROSACEA.—Neumann (*Allgem. Wiener Mediz. Zeitung*, no. 37, 1876) has found excellent results from brushing the affected skin with a solution of one part of carbolic acid in three or four parts of alcohol. The application is made three times a week, and produces no cicatrix. The treatment is not applicable when there is much thickening and oedema.

PICK ON THE RELATION OF DIABETES TO SKIN-DISEASES.—Pick (*Medicinisch-Chirurgisches Centralblatt*, no. 34, 1876) describes cases of pruritus and furunculosis, in which these maladies were developed in diabetic patients. He believes that the diabetes and skin-lesions are produced by a common cause, and that the origin of both is to be found in a disordered condition of the brain. Some cases of skin-affection are, on the other hand, the effect of the diabetes. Amongst these are instanced certain forms of eczema, xeroderma, pruritus, furunculosis, and a special affection of the mucous membrane of the mouth, which he designates epitheliosis mucosæ oris.

OPHTHALMOLOGY AND OTOLOGY.

SCHELL ON AN AUTOMATIC METHOD OF OPENING THE EUSTACHIAN TUBE AND AIRING THE TYMPANUM.—In the *American Journal of the*

Medical Sciences for July, 1876, Dr. H. S. Schell, of Philadelphia, describes a new method for inflating the tympanum, which, he says, he has employed with advantage for more than a year. The method is based upon the fact, that during the act of yawning, and especially if the mouth be kept closed, as in a suppressed yawn, a sensation of movement or slight clicking sound will be experienced in the ears. Dr. Schell thus describes his plan.

‘I generally direct the patient to keep the lips tightly closed, and to draw down the throat, and even to separate the jaws slightly, as if trying to yawn without being observed. The effort usually produces the yawn itself, and if, immediately after the long inspiration which accompanies the act, or at the beginning of expiration, the nostrils be closed with the fingers, air will be felt to fill the tympanic cavities. The tympanum will remain inflated for some time, often uncomfortably, if any amount of force have been used, but may be quickly eased by swallowing the saliva once or twice with the mouth shut. The obvious effects of the inflation can be limited to either ear, by closing the external meatus of the other tightly with the unoccupied hand. The *modus operandi* of the process is as follows. In the act of yawning, as observed in a mirror, the base of the tongue is depressed or fixed, the soft palate is elevated or fixed, and the isthmus of the fauces is very much narrowed by the posterior pillars being strongly drawn towards the middle line. From the shape of a broad arch the isthmus faucium shrinks into a slit half an inch wide, and the posterior pillars become straight and rigid. While this narrowing is in progress, a clicking sound is heard in the tympanum, evidently owing to the separation of the walls of the tube, and then inflation may be easily performed. It seems from this that the principal, if not the only agent in producing this effect, is the palato-pharyngeus muscle, through that part of it which arises from the cartilage of the Eustachian tube, the so-called salpingo-pharyngeus. The salpingo-pharyngeus does not necessarily contract simultaneously with the main portion of the palato-pharyngeus, for I find that in my own person I can voluntarily narrow the isthmus faucium to about half an inch in width without affecting the Eustachian tube, unless I make the effort to yawn. In the former case, the muscle expends its force upon the thyroid cartilage and pharynx, and the base of the tongue rises. In the latter, the base of the tongue being fixed, the muscle acts in the opposite direction, the salpingo-pharyngeus has a *point d'appui*, and the tube is pulled open. But the influence of the palato-pharyngeus upon the soft palate is at the same time opposed by the levator palati; it may be also to some extent by the tensor palati, for the palate is raised or fixed, and, as the latter two muscles have some attachment to the cartilage of the tube, it is possible that they also contribute something to the particular result in question. At all events, in the effort to yawn all the muscles of the throat apparently participate, but the peculiarity which accompanies the opening of the tube occurs when the action of the palato-pharyngeus is most evident. As the patency of the Eustachian tube produced in this way is not merely momentary, but continues during the yawn, there is no need of hurry, and inflation can be made only deliberately, and softly or strongly as occasion may require. It is only necessary that it should be done while the yawn lasts, and not after it is over. In many cases it is not necessary to in-

flute at all, the mere opening of the mouth of the tube being sufficient to let the air rush into the tympanum.

With regard to the occasions for the use of this process, Dr. Schell has found it very useful in the inflammatory conditions of the middle ear, which are accompanied by constantly accumulating mucous or purulent secretion. If there be at the same time perforation of the membrana tympani, the discharge of the secretion into the external meatus may be secured at frequent intervals, and the entire aural tract may be kept clean by the application of medicated washes. To apply these, it is only necessary to draw a portion of the liquid up the nose until it is felt to run into the pharynx, to hold the head inclined so that the diseased ear is underneath, and to practise inflation as before. In cases of deafness resulting from closure of the tube from recent swelling about its pharyngeal extremity, this method offers an easy means of obtaining patency of the canal from time to time without pain or annoyance.

MOOS ON CHANGES IN THE LABYRINTH IN INFECTIOUS DISEASES.—In the *Archives of Ophthalmology and Otolaryngology* for August, 1876, is a paper by Dr. Moos of Heidelberg on the changes in the labyrinth accompanying infectious diseases. The author commences with some remarks on the literature of the subject, and then gives full reports of six cases of typhoid fever, in four of which *post mortem* examination revealed changes in the labyrinth. Dr. Moos finds as the result of microscopical examination, that in ileo-typhus the entire labyrinth is very often affected on both sides. Any portion may be attacked. The parts which suffered in all the cases were the utricle, saccule, ampulla, and lamina spiralis membranacea. The parts exceptionally involved were the semicircular canals and the zona ossea. The parts most essential to good hearing were regularly affected. Whether there exists any connection between this and certain peculiarities in the normal distribution of blood-vessels Dr. Moos cannot at present decide. Histologically the affection consists of an infiltration of lymphoid cells or an infiltration of small cells. With the exception of one case in which fat granule-cells were found besides the small cells, with the same anatomical distribution and in almost equal abundance, the latter was the only and the constant new formation.

Before interpreting these facts, Dr. Moos narrates some more cases, two of total deafness after typhoid fever, one of inflammation of the labyrinth after scarlatina, and one of purulent inflammation of the labyrinth in variola. The author then considers the question whether in the pathological changes found in the labyrinth of typhoid patients we have to do with merely a state of irritation (an inflammation), or whether there is a special new formation peculiar to typhoid. In support of the view that there is a new formation special to typhoid, the following reasons are adduced. In the first place the affection occupied both sides uniformly, even in one case where it was impossible to speak of any transference of the morbid process from the middle to the inner ear. Besides, we ought to consider the resemblance borne by these processes to changes occurring in other organs during typhoid fever, such as have been observed not only in the glands of the intestinal mucous membrane, and in the mesentery, but also in the liver, the kidneys, and in the peritoneum by Wagner, Friedrich, and others.

In four of the cases in which a purulent inflammation of the tympanic cavity also existed, it might be assumed that the inflammation was simply propagated from the tympanic cavity through the wall of the labyrinth to the cutaneous labyrinth, especially as the membranous tissues of the vestibule lying next to the tympanic cavity were often the most seriously affected (even the periosteum of the vestibule being attacked in some cases); and besides, the changes in the labyrinth did not differ in any respect from those of the first stage of inflammation.

In the case of scarlatina, the state of the labyrinth could be accounted for in like manner.

Clinical reasons support the view of the translocation of the inflammation from the tympanic cavity. If, however, the inflammation of the labyrinth be regarded as propagated from the tympanic cavity it may still be possible that the tympanic affection stands in a relation of cause and effect to the typhoid process. Catarrhal affections of the mucous membranes in general are not rare in typhoid fever. Having stated the possible modes of explanation, and pointed out the fact that inflammation in the labyrinth is common in typhoid, Dr. Moos leaves for future decision the question whether in such cases we have or have not to do with a specific typhoid process, and concludes his interesting and suggestive paper by describing the various possible modes of termination of the affection of the labyrinth. If this affection be an inflammatory irritation, the latter may increase in its course to a purulent inflammation; or a fatty breaking down and complete resorption of exudation may occur; the latter may be the case even when we have a typhoid new formation, or there are opacities, thickenings, or atrophy of the affected tissues; or, as in the intestinal follicles and the mesenteric glands in typhoid fever, there may be necrosis or ulceration.

In applying these various possible results to those disturbances of hearing accompanying typhoid, which offer only negative symptoms during life we may expect to find: 1. Gradual and spontaneous disappearance of functional disturbance of hearing; or, 2. Persistence of some degree of deafness, with or without subjective noises; or, 3. Complete unilateral or bilateral disturbance of function.

BOWEN ON DISEASE OF THE MIDDLE EAR INDUCED BY THE USE OF THE NASAL DOUCHE.—The *New York Medical Record*, September 9, 1876, contains a record by Dr. Wm. Bowen of six cases of disease of the middle ear which appear to have been due to the use of the nasal douche in the treatment of naso-pharyngeal catarrh. This method of treatment would appear to be in very common use in America, it being a simple, efficacious, and apparently safe remedy for an affection to which Americans are peculiarly subject. Dr. St. John Roosa, however, called attention to the production of supuration of the middle ear by a current of fluid thrown by the douche into the Eustachian tube and the delicate parts beyond. The late Mr. Hinton also mentioned a case in his 'Questions of Aural Surgery.' Dr. Bowen's remarks on the *modus operandi* of this cause of aural disease are as follows. 'The structure of the lining mucous membrane of the Eustachian tubes is such as to be antagonistic to the passage of fluids from the pharynx to the cavity of the tympanum. The ciliated epithelium moves downwards towards the pharyngeal openings, and as the walls normally are in apposition in the

greater portion of their length, except in connection with the act of swallowing, there is requisite a certain amount of force to inject a fluid to the cavities of the middle ear behind the drum-head. The action of the douche depends upon the physiological action of the muscles of the palate, which close the lower part of the pharynx, and prevent the passage downwards of the medicating liquid, which, entering the nostril on one side, filling the nasal cavity and upper part of the pharynx, escapes through the opposite nostril. If there is undue patency of the tubes the current may be forced up against the cilia, and possibly reach the tympanic cavities, although inflammation without its going so far, but on account of extension of tubal irritation. The more frequent source of danger, however, is the act of deglutition which may occur while the pharynx above the palate is filled. The mouths of the Eustachian tubes simultaneously open, and the hydrostatic action occurs along their course. That this occurs frequently without any dangerous results following, I am convinced, but the danger always exists. Fluids thrown into the tympanic cavities may be retained until absorbed. According to Mr. Yule's experiments, the resistance of the tubes is greater from above downwards through an imperforate drumhead required force sufficient to raise a column of mercury four inches. Whatever is forced upwards by pressure probably remains in great part until absorption takes place. When the current of medicated fluid from the douche is passing through the nostril into the pharynx, the act of deglutition is to be strenuously avoided, and this precaution is insisted on by the advocates of the douche as a means of treating catarrh, it being asserted that with proper care the mishap is impossible.' In spite of the utmost attention, however, portions of the fluid may escape into the throat below the palate, and swallowing involuntarily taking place the risk of entrance of some of the solution into the open tubes is great, and upon the distance which it penetrates the risk of sac disturbance depends. When this risk is considered fully, the grave consequences of suppurative inflammation being remembered, it becomes evident that the apparently simple and useful nasal douche is really a dangerous instrument, and its use should be discarded, except under conditional and exceptional circumstances. [In a paper read before the British Medical Association, at Sheffield, in August last, Mr. Lennox Browne drew attention to the dangers of the nasal douche, and its liability to cause disease of the middle ear. In the place of the anterior nasal douche he advised the use of the posterior nasal douche, and of vapour-inhalations by mouth and nose.—*Rep.*]

MARTIN ON A FOREIGN BODY IN THE GLOBE OF THE EYE FOR FOURTEEN YEARS.—In the *Recueil d'Ophthalmologie* for October, 1876, Dr. Martin of Marseilles relates a very remarkable case. The patient, aged forty-five, presented himself at Dr. Martin's clinic about four years ago. He complained then of violent pains in the left eye, radiating towards the temple and frontal region, photophobia, lacrymation, etc. His medical attendant had treated him with antiphlogistics, etc., for some weeks, and put down the affection as due to a rheumatismal diathesis. The patient stated that for a long time he had been taken suddenly every year, in spring and autumn, without apparent cause, in the same way,

with frightful pain, which obliged him to keep his room for a month, and undergo severe treatment. Surprised at this account, Dr. Martin examined the eye carefully, and, in spite of acute symptoms of iritis, employed oblique illumination. 'This examination demonstrated the existence of a small blackish pyriform body about the thickness of the head of a pin, with its base on the crystalline and inferior and external border of the pupil; it manifestly projected at one point. The cornea was perfectly healthy, and presented no trace of an old wound. The little tumour in no respect resembled a tumour of the iris. I immediately thought of a foreign body, and informed the patient of the result of my examination and my diagnosis. I could not convince him for some time, and it was not until he had exercised his memory that he remembered that his first ocular trouble followed a blow received in the workshop (marble works). He told me then that fourteen years previously he had been obliged to remain in a dark room, and that every year since that time he had had these internal ocular inflammations. The patient, now convinced, wished to be relieved. The only indication was to remove the foreign body; to this he consented, and the operation was performed the same day.' The cornea having been punctured at its inferior external border with a large lance-shaped knife, the aqueous humour was allowed to flow slowly out, for fear of the foreign body disappearing behind the iris. The forceps was then introduced into the anterior chamber, and the hard and black body, which consisted of a triangular fragment of marble, was easily seized. A slight protrusion of the iris occurring, the operation was completed by the excision of the protruded portion. The sequelæ were simple, the pains disappeared the same day, and at the end of a week the patient left perfectly cured.

For five years the eye has been well, and vision completely preserved.

W. DOUGLAS HEMMING.

POLITZER ON THE TREATMENT OF CHRONIC PURULENT CATARRH OF THE MIDDLE EAR.—After a long experience of the various astringents used in chronic purulent otorrhoea, Prof. Politzer gives in a short paper in the *Archiv für Ohrenheilkunde* for April his opinion on their comparative efficacy. Happily, he gives a decided opinion, and it is in favour of powdered alum and nitrate of silver. His method of applying these is as follows. The ear having been cleared of secretion by Politzer's method, or by the catheter, ten to fifteen drops of a nitrate of silver solution, of a strength of one of nitrate to ten of water, are passed into the ear, the patient inclining his head so that the fluid gravitates into the cavity. After it has remained there from one to two minutes, the surplus is washed out with lukewarm water. This is repeated daily eight or ten times; and, should the otorrhoea not then have ceased, powdered alum is blown into the ear by means of a quill or catheter, care being taken that it reaches the drum and lining membrane of the middle ear. This is left for two or three days, and then examined. Should the alum be then lying dry on the membranes it is not disturbed, but allowed to break down and fall out of itself. Should it be found moist and mixed with secretion, it is washed carefully out, the parts thoroughly dried, and nothing done for twenty-four hours. If secretion then exist, alum is again introduced and treated as before.

[This method has been often used in England since Dr. Politzer proposed it in 1868, and with good results. The use, however, of such concentrated solutions of nitrate of silver is not always safe, and consequences arise which are distressing both to patient and to practitioner. The application of the powdered alum is followed in some cases by an irritable affection of the skin of the meatus. These results can be avoided by limiting the use of the silver solution to the parts to which it is desired to apply it, by soaking some absorbing material in the solution, fastening it on a probe, and so applying it, and by limiting the application of the alum to the affected membranes. These minutiae of application can be carried out in private practice, but not in a large hospital clinique.—*Rep.*]

VOLTOLINI ON A NEW METHOD OF RHINOSCOPY. Professor Voltolini, of Breslau, describes in the *Monatsschrift für Ohrenheilkunde* for August a method by which the floors of the nasal cavities and the pharyngeal orifices of the Eustachian tubes may be examined. These regions are, in favourable cases, seen by the methods already in use; but it is only in exceptional cases that even one well practised in rhinoscopy gets a view of them. The method which Voltolini proposes is simple. The patient places and keeps his tongue in the position required, and the uvula is also set aside by any of the usual methods. The surgeon employs two separate laryngeal mirrors, their sizes corresponding to the pharyngeal space about to be examined. The first mirror introduced must have a longer handle than the usual laryngeal mirror, and be capable of being bent as desirable. A slight curve is given to it at the part next the handle, so that it passes over the tongue easily; and at the part which reaches the posterior pharyngeal wall it is bent to a right-angle. The mirror at the end is passed upwards to the basis cranii, and so placed opposite the posterior nasal orifices. The second mirror is the usual laryngeal mirror, the back of which is pressed against the handle of the other where it first ascends into the pharyngeal space. Light is thrown upon the shorter mirror, which reflects it to the longer, which again reflects it to the spot to be examined, an image of which is returned in the same way.

URBANSCHITSCH ON THE INFLUENCE WHICH THE POSITION OF THE HEAD HAS ON THE INTENSITY OF A CURRENT OF AIR DRIVEN INTO THE EUSTACHIAN TUBE.—The July number of the *Monatsschrift für Ohrenheilkunde* contains a paper on the above subject by Dr. Urbanschitsch of Vienna. He finds that in several cases Politzer's method was effectual only when the patient's head was inclined to one or other shoulder. Manometrical observations gave the same result. When a manometer was attached to each meatus, and a current of air driven into the naso-pharyngeal space, the action on the column of fluid was equal in both manometers, the head being erect; but on inclining the head to a side, it was often found that the fluid in the manometer attached to the ear which was uppermost was more affected than that in the ear pointing downwards.

To determine if the cause of this could arise from some change in the nasal spaces, he constructed a wooden model of these, and by experiments with this model concluded that the position of the head had no influence on the current as it passed through

them. He concludes, therefore, that the position of the head acts on the opposition which the mouth of the Eustachian tube offers to the rush of air against it. He believes that there is an increased action of the tube-moving apparatus on the uppermost tube, whereby the opening of the tube is more favoured, and therefore a decreased opposition to the entrance of air, when the head is inclined to the side; while the muscular structure of the other tube is unaffected.

MOOS ON THE CONNEXION BETWEEN EPILEPTIFORM PHENOMENA AND DISEASES OF THE EAR.—In the *Archives for Ophthalmology and Otology* for 1876 is the report of a lecture by Dr. Moos on the above subject, translated by Dr. Burnett, of Philadelphia. He considers that the diseases of the brain and its appendices, which occur as complications in diseases of the organ of hearing, may be divided into two groups, viz. (1) those diseases which are to be regarded as the result of a direct passage to it of an inflammatory process; (2) those diseases which, according to the present status of nerve-pathology, we are compelled to believe to arise by being centrally conveyed from the seat of irritation, and produce processes in the brain which are manifested again peripherally. The latter are the affections of which Dr. Moos speaks in this paper, and to them he applies the term reflex neuroses. These reflex neuroses consist of attacks of sneezing, coughing, vomiting, epilepsy, hemiplegia, and psychoses. After giving a short review of the literature of the subject, he gives an account of a case of reflex epilepsy observed by him lately. A boy, eight years old, was brought to the aural clinique on account of frequent attacks of ear-ache, discharge, and deafness. Between these attacks of ear-ache the patient had attacks of unconsciousness, ushered in regularly by 'great sleepiness and great diminution of the hearing, and sometimes vertigo, headache, and palpitation of the heart.' These attacks of unconsciousness lasted from two to three hours, during which the patient did not fall, and had no convulsions, but remained unconscious and speechless, his gaze being fixed. The still greater diminution of hearing was so marked in the later stage of the disease, that when it occurred the relatives of the child predicted one of the attacks just described with invariable certainty. The attacks disappeared with vomiting, and then consciousness returned. The objective examination gave the following. On both sides the membranæ tympanorum were considerably drawn in, and they appeared tightly stretched over the promontory. The short process of the hammer, and the posterior fold of the membrana tympani, were sharply prominent, and the manubrium appeared perspectiveforeshortened. These symptoms were caused by an excessive catarrhal disease of the nares and naso-pharyngeal space. This being treated in the usual method, and inflation of the tympanic cavities being effected by Politzer's method, and by paracentesis, all the reflex symptoms passed off, and no epileptiform attack had occurred since the commencement of the treatment till the patient was last seen, nearly a year afterwards. No other treatment was adopted, and Dr. Moos thinks that in this case the *post hoc* must be admitted to be *propter*.

W. LAIDLAW PURVES.

SPAMPINATI ON TREATMENT OF DILATATION OF THE LACRYMAL SAC BY INJECTION OF PERCHLORIDE OF IRON.—Dr. Spampinati (*Movimento*

Medico-Chirurgico of March 7, and *Annali Universali*, August), in cases of narrowing of the nasal duct with dilation of the lacrymal sac, follows the process which he has seen employed by Del Ponte, namely, puncture of the sac and dilatation with a lead or catgut sound. Spampinati endeavours to obtain contraction of the lacrymal sac by injecting perchloride of iron: A lady had a soft lacrymal tumour of the size of a small nut. On pressure, mucus mixed with tears escaped through the puncta lacrymalia. The skin covering it was of unusual colour. Having opened the lacrymal sac, he ascertained that the nasal duct was obstructed by fungous growths. He applied probes dipped in a solution of crystallised nitrate of silver in water (0.75 per cent.). After four months there was marked improvement, but the lacrymation continued, and the tears collected in the dilated sac. Spampinati then determined to inject with an Anel's syringe solution of perchloride of iron mixed with two parts of water, removing the liquid by the syringe after a few minutes. After the applications the lacrymation disappeared, and neither mucus nor tears collected in the sac. The same result was obtained in another patient. In both the effect was permanent, the disease not having reappeared in the first patient a year, and in the other six or seven months, after the treatment. The injections were used every day, the liquid being allowed to remain in the sac five or six minutes, and then removed by means of the syringe.

REPORTS OF FOREIGN SOCIETIES.

IMPERIAL ROYAL MEDICAL SOCIETY OF VIENNA.

October 20, 1876.—*Skin-Eruption from Bromide of Potassium*.—Dr. Pinsker, of the Leopoldstadt Children's Hospital, in presenting a patient, said that the occurrence of cutaneous eruption after the use of bromide of potassium had been already described by Voisin, Weir Mitchell, and Neumann; but still he regarded the case which he presented as

rare. The patient was an idiotic boy aged ten. From his second year he had suffered from epileptic attacks, at first occurring at rare intervals, afterwards more frequently; and a year ago his mother sought medical advice. Five grammes (seventy-five grains) of bromide of potassium were administered daily, with occasional interruptions. In December, 1875, he was sent to the Children's Hospital as having small-pox. There was an abundant pustular exanthem on the forehead and temples and on the trunk and limbs, besides some vesicular exanthem. The history and course of the case led to the diagnosis of bromine-acne. The patient was dismissed after having been four weeks under treatment. He was again treated by bromide of potassium, in daily doses, according to the mother's account, of 45 grains. The eruption, which had lasted three months, was treated, without effect, by diachylon ointment. Within the last ten days, under purely expectant treatment, there had been a marked decrease both in the extent and the intensity of the eruption.

The Hypodermic Treatment of Syphilis.—A paper on this subject was read by Dr. Neumann. After giving a short historical sketch of the method of treatment by ingestion, and of the appearance which the various preparations of mercury produced on the skin, he proceeded to speak of the action of mercury-albuminate and mercury-peptone. He had never met with abscess or sloughing; when the pain was considerable, it depended greatly on the vulnerability of the individual, on the dexterity with which the operation was performed, and on the purity of the solution and of the cannula. An estimate of the comparative value of the fluids used for injection may be formed by selecting (*e.g.*) the skin of the back or of the side of the chest or of the buttock, and injecting into one part albuminate of mercury, into another mercury-peptone, into another an aqueous solution of corrosive sublimate, or a combination of this with morphia. It will then be found beyond doubt that the solution in albumen, recommended by Bamberger, produces the least pain and the least reaction. It is not perfectly painless; but neither abscess nor sloughing of the skin have been observed to follow the use of the solution, if pure. Dr. Neumann gave the following as the reason why the solution in albumen produces less pain than the aqueous solution. It is known that many irritants lose their caustic action when dissolved in oil, glycerine, or albumen. This is daily observed in the case of carbolic acid and caustic potash. The same is the case with corrosive sublimate, though here chemical conditions must have some influence, for the absorption of the sublimate into the juices of the organism occurs only as a result of its combination with albuminoid substances. Corrosive sublimate dissolved in water must combine with the albumen in the subcutaneous connective tissue, and this combination can only be carried into the circulation after having undergone decomposition, just as corrosive sublimate in the stomach combines first with the albuminous substances in that organ, and, if there be not enough of these, with the mucous membrane of the stomach itself, so as to produce irritation. The advantages above described as attending the use of albumen and also of peptone solutions were not met with when the injections were made into other parts than those mentioned, such as the arms or hands, or into indurated tissue. With regard to peptone-mercury,

the following was the result of experiments made on several patients. As is well known, peptone is a white amorphous body, soluble in water in almost any proportion. It causes very little pain, and produces less reaction at the point of injection than the albuminate. As regards the number of injections, from twenty to fifty are necessary to cause the disappearance of the various manifestations of syphilis. Dr. Neumann found, with other observers, that the vesicular, papular, and squamous syphilides disappeared most rapidly; one case only, of chronic macular syphilide, required fifty injections; while the eruption with small particles, and also enlarged lymphatic glands, was slow in disappearing. In cases of indurations not yet followed by general symptoms, the injections did not prevent the eruptions from appearing. Psoriasis palmaris and plantaris was rapidly relieved by the injection. Injections into indurated tissue produced circumscribed sloughing. Affections of the mucous membrane and syphilitic tubercle arranged in groups, demanded a larger number of injections. Gummata resisted injection remarkably; whether a result followed rapidly in cases of syphilitic iritis, the author could not state from his own experience. Lewin has described brilliant results in this affection. In one case of double iritis, little or no effect was produced. Dr. Neumann had injected only three centigrammes, when he was obliged to desist in consequence of cedematous swelling at the point of injection and consecutive cedema of the eyelids. He had used the injections sometimes once, sometimes twice a day, and had never met with toxic symptoms. Stomatitis occurred in two patients only, after seven and fifteen injections; the only preventive measures prescribed were, to cleanse the teeth carefully, and to rinse the mouth frequently with water. The injection treatment does not secure against relapses, but whether they appear more rapidly cannot yet be decided. Lewin observed 30 per cent. of relapses, which were, according to his statement, less severe than after other methods. The slight reaction which follows the injection of pure albumen or peptone solutions of mercury, the accuracy with which the dose can be measured, the small quantities (on an average 15 to 25 centigrammes) required to subdue the syphilitic symptoms, the freedom of the stomach from irritation, especially in debilitated persons, the cleanliness of the application, the rarity of stomatitis, and the rapidity with which cure follows the use of sufficient doses, are evident; and the rapid elimination of the mercury must relieve even the antimercurialists of fear of mischief. Dr. Neumann had in his cases not met with certain symptoms described by others, as being produced by this method, such as elevation of temperature (to 104° Fahr.), increased frequency of pulse, sleeplessness, and profuse diarrhœa.

On Mercury-Peptone and on Flesh-Peptone.—In reference to Dr. Neumann's paper, Dr. Bamberger observed that two circumstances led him to seek a new preparation instead of the albuminous solution. The solution was rather difficult to obtain in the necessary state of clearness and purity, and required long and careful filtration; and secondly, it could be kept only for a limited time. Although as clear as water at first, the fluid in four or six weeks become turbid, and threw down an albuminous precipitate. A body allied to albumen, peptone is readily soluble in water, resists the actions of heat, alkalies, and acids, can be readily filtered, and

combines with mercury. A 5 per cent. solution of corrosive sublimate, and a 20 per cent. solution of common salt were made. With one gramme of flesh-peptone, in the form of a yellowish crystalline powder, 50 cubic centimètres of water, and 20 cubic centimètres of solution of corrosive sublimate were mixed. The turbidity which resulted was removed by the addition of 15 or 16 cubic centimètres of the solution of chloride of sodium. The solution contained 1 per cent. of peptone-mercury. It can be kept for some time; a specimen prepared in the beginning of July remained clean. If any precipitate should appear, the supernatant clear fluid must be poured off. The results of injecting this solution had hitherto been largely satisfactory; it was not painless, because, just as distilled water does, it produced pains by distending the subcutaneous tissue; it should be injected slowly, and the injected fluid should be at once distributed by pressure. Dr. Bamberger had at first prepared the peptone by the action of pepsin on finely chopped meat, but latterly he had obtained it from London. It was an excellent therapeutic agent, relieving the stomach of much work, especially when the absorbent property of the organ was alone left. It was also useful in the gastric and intestinal affections of children, in ulcer of the stomach, in convalescence for acute diseases, etc. He hoped that it would soon come into extensive use.

October 27. *Comminuted Fracture of the Femur; Fatty Embolism in the Pulmonary Artery.*—Professor Heschl showed a portion of bone removed from a man who had died a few days previously in the General Hospital. He had been admitted under Dr. Billroth's care in consequence of fracture of the thigh by a fall; the constitutional symptoms were at first very slight, but he soon died, with marked symptoms of septic poisoning. The left femur, at the juncture of the third and last fourths, had sustained a comminuted fracture, which extended into the condyles. He had not only fallen, but a heavy body had fallen on him, a circumstance which always produces considerable destruction of the marrow. At the necropsy, the organs in general were found to be healthy; but the lungs, which presented no abnormal appearance to the naked eye, were found, when examined with the microscope, to have numerous fat-drops in the capillaries and arterioles. Dr. Heschl remarked that similar appearances had been described by others as following injuries of the bones, with destruction of the marrow, and that in many cases fatty embola had been found in the arteries of the brain.

The Function of the Nerves of the Blood-Vessels.—After referring to the labours of Ludwig, Cyon, Ostrumoff, and Goltz, Professor Stricker described the researches which he had made on the so-called vaso-dilator nerves, in order to ascertain their origin, and whether it was possible to isolate them. He divided the spinal cord of dogs between the seventh and eighth dorsal vertebræ; and, when the animals had recovered, he applied various irritants to the roots of the spinal nerves, and observed, by means of a thermometer fastened between the toes, the effects produced on the cutaneous temperature. The last pair of lumbar nerves was specially examined. He separated the posterior from the anterior root, tied the former, and divided it behind the ligature. If the animal's paw were at rest, and showed a constant temperature (between 68° and 71.5° Fahr.) it was observed that, when the nerve was irritated by the

application of a second and a third ligature, the temperature always rose rapidly to 86° or even 95° Fahr. This rise of temperature lasted only a few minutes, proving that it was the result of irritation and not of paralysis of the nerves of the vessels; in the latter condition, the elevations of temperature often continue through an entire day. It was a remarkable fact that the posterior or venous roots conveyed centrifugal impulses. Dr. Stricker here called to mind the observation that neuralgia begins with hyperæmia, and remarked on the connection between disease of the nerve-ganglia and herpes zoster. He found also that the nerves of the vessels pass directly into the sciatic, and that this nerve receives but an inconsiderable number of vaso-dilator nerves from the roots of the spinal nerves above it.

Simulated Diabetes.—Dr. Abeles said that in 1875 he had under treatment in Carlsbad a lady, aged twenty-eight, who was said to have diabetes mellitus. She had first had hæmaturia. On examining the urine, which had a specific gravity of 1040, he at first found no sugar; but, after a few days, he found 9 per cent of sugar. Appropriate diet was prescribed. At the next examination, the urine had a specific gravity of 1074, and the polarising apparatus indicated 22.5 per cent. of sugar; which, however, acted on copper or bismuth solution only when boiled with dilute acid. All this, with other evidence, convinced Dr. Abeles that he had to deal with cane-sugar, which was mixed with the urine. The patient's urine was obtained without her knowledge, and was always found to contain a considerable quantity of cane-sugar; once only, shortly before her departure, it was free from sugar. The following year she returned; and her urine, on examination, was found to contain grape-sugar. Some which was removed by the catheter contained 16 per cent. It was suspected that the patient herself introduced the sugar into the bladder. She otherwise presented no hysterical symptoms. The urine, examined shortly before her departure, was still found to be of abnormally high specific gravity and to contain large quantities of grape-sugar.

November 3. *The Supracondyloid Process in Man.*—Dr. C. von Patruban had for some years collected statistics regarding the supracondyloid process, the relations of which to the muscles, vessels, and nerves, were almost constant. The subject was of practical importance, inasmuch as persons who had this process—especially if they happened to have glandular swellings—were sometimes regarded as syphilitic, and treated with mercury. A supernumerary head of the pronator teres always comes from it; and the brachial artery with its venæ comites and the median nerve and lymphatics always pass behind it. M. Gruber has shown that this process forms a canal, to which he gives the name of canalis fibro-osseus. Dr. von Patruban showed the process in a number of preparations.

A Rare Injury of the Ankle-joint.—Dr. von Patruban described this case. A strong well-nourished woman, aged forty-five, was removing an iron stove, and in descending a ladder with her burden, caught her foot between two bars. When she regained consciousness, she observed a wound two inches and three-fourths long on the dorsum of her right foot. The surgeon who was called in sent for Dr. von Patruban, who, on removing the coagula, found the body of the astragalus lying detached, and removed it. The foot was dislocated outwards. The displacement was reduced, and the wound

cleaned and dressed, the foot being put up in an elevated position. At the end of six weeks, the woman had good use of the foot.—Dr. Dumreicher related two cases of complicated dislocation. A woman, while on a ladder, slipped, and fell from a height of about three feet, on the outer side of her foot. On the inner side of the foot there was a lacerated wound, in which lay the astragalus, connected only by thin fibres with the rest of the foot. The bone was removed, and the limb put up in a Petit's boot; recovery took place in four weeks. The second case was that of a man who, in descending from a wagon, came down on the outer side of his foot, which was dislocated, and could not be replaced. When he was seen, some days after the injury, there was considerable swelling, with sloughing of the dorsum; a comminuted fracture of the astragalus was detected by means of a probe. Five pieces were removed, and recovery took place in five weeks.

Myxoma of the Labia Pudendi.—Dr. Patruban showed a myxoma, which he had removed from the labium of a female, aged sixty. It commenced as a sessile pigmented wart, which gradually increased to the size of a small apple, and became provided with a pedicle several centimetres long. This last circumstance was, in Dr. Patruban's opinion, very exceptional, and difficult of explanation.

MEDICAL SOCIETY OF BERLIN.

May 17, 1876.—*Rare Disease of the Larynx.*—Dr. B. Baginsky showed a boy, aged twelve and a half years, the subject of a diseased condition of the larynx and trachea which he had not found described in literature. The disease occupied the larynx and trachea, which could be examined by sunlight or by good artificial light as far as the eighth or ninth ring. For some time the boy's mouth had had a disagreeable smell, and he had coughed up offensive greenish masses; in other respects his health was good, he was fairly well developed, and there was no family history of scrofula or syphilis. There was slight pharyngeal catarrh, and swelling of both lower nasal fossæ. On examination with the laryngoscope, between the true vocal cords and on the wall of the thyroid and cricoid cartilages, and especially in the trachea, there were seen soft greenish-grey masses, firmly adherent to the mucous membrane, from which small portions were occasionally dislodged by coughing. Between them the mucous membrane was denuded of its epithelium, eroded, and bleeding readily. Treatment by inhalations of carbolic acid, solvents, and astringents, and the internal use of syrup of iodide of iron, had as yet been without result. Microscopic examination of the green masses showed a quantity of epithelium that had undergone fatty degeneration, with crystals of tyrosin and small moving corpuscles. The disease had a great resemblance to nasal ozæna, and the condition called by Waldenburg pharyngitis impetiginoides. Dr. Baginsky believed that it was not analogous to putrid bronchitis; in this disease, the expectoration was very abundant and fluid, while in the present case it was very scanty. From the resemblance to nasal ozæna, he would propose for it the name of laryngo-tracheal ozæna. The prognosis was unfavourable, as perichondritis was to be feared. Dr. Baginsky also showed in the same patient a specimen of benign mycosis of the pharynx.—Herr B. Fränkel said that he had several

times seen the patient. He had seen several cases of ozena of the larynx, and had referred to them in his article on Ozena in Ziemssen's *Cyclopædia*. But, until he saw this case, he had never met with one in which the foetid masses were below instead of above the vocal cords. As regards the foetid masses in the trachea, he had found much fatty epithelium and fungi; and also crystals of tyrosin. He could not determine whether there was any connection as regarded cause between the foetid deposits and the mycosis of the pharynx. However this might be, leptothrix was present in both.

May 31. *Wound of the Hand*.—Herr Bardeleben described the case of a woman who had been wounded by a sharp hatchet during a quarrel with her husband. On her admission into the Charité Hospital, she had a gaping wound on the forehead, reaching to the bone; and there were numerous wounds on both hands, especially the right. The metacarpal bone of the thumb was cut through, and many of the carpal and carpo-metacarpal articulations were laid open, and several tendons were divided. When Herr Bardeleben saw the patient, every preparation had been made for amputation; but he determined to trust to antiseptic dressings, and to endeavour to preserve the hand. The result was that recovery took place with a very useful hand; the fingers retaining a considerable amount of mobility in spite of the injury of the tendons. No sutures were applied to these.

Morbid Conditions following Vaccination.—Herr Goldschmidt showed a child which he had vaccinated on the left arm a fortnight previously. The pustules were at first normal, but assumed a phagedænic character, and similar ones were observed below the right eye and on the labia pudendi.—Herr Lewin remarked that the pustules on the labia were very like broad condylomata. The case might possibly be of syphilitic origin.—Herr B. Fränkel could not see the resemblance to condylomata. The pustules in the labia and below the eye had distinctly the characters of vaccine pustules.—Herr O. Simon believed that the labia and face had been infected by means of the child's finger. He did not believe that the affection was syphilitic.—Herr Goldschmidt could not acknowledge that syphilis had been communicated. In a number of other children vaccinated with the same lymph, the vaccine had ran a normal course. The child was perfectly well when it was vaccinated.

June 14. *Aphonia*.—Dr. B. Fränkel showed a man who had aphonia, but could speak aloud when his tongue was protruded. The affection was said to have come on after a severe febrile illness. On laryngoscopic examination, nothing abnormal could be found, and Dr. Fränkel believed the affection to be of hysterical nature.

Miliary Tuberculosis of the Pharynx.—B. Fränkel read a paper on this subject.

Influence of the Nerves on Diseases of the Skin.—Herr G. Lewin made a communication on this subject, and exhibited a patient.

June 28. *Case of Intra-Uterine Repair of Epispadias with Fissure of the Bladder*.—Herr E. Küster described this case. A child named Arthur Schulz, aged 1 $\frac{3}{4}$ years, had a perfectly developed epispadias with an urethral furrow on the upper surface of a shortened penis; there was also fissure of the symphysis pubis, and a wide gap in the abdominal muscles, the umbilicus being absent. The urethra, however, had its upper wall represented by

a thin cicatrised mass; there was a ligamentous mass at the symphysis, and the anterior wall of the bladder was represented by a cicatrix. The permanent incontinence of urine led the parents to bring the child for advice. At the root of the penis there was a narrow stricture, through which only the smallest catheter could be introduced. The existence of a vesical space could be distinctly made out: the sphincter vesicæ was present, but was cleft. Analogous occurrences are not wanting in the human body; intra-uterine repair of hare-lip and cleft palate have been met with in several cases.

ACADEMY OF MEDICINE OF PARIS.

October 24. *Accidents in Hunting*.—M. Galezowski read a paper on accidents in hunting affecting the eye, and the means of avoiding them, by the use of rock crystal, or toughened glass spectacles. Experiments made by him on such spectacles showed that the projectile ricochets, and does not touch the eye, which is thus preserved.

Gastrostomy.—M. Verneuil made an interesting communication on a case of gastrostomy. This operation, proposed and originally performed by M. Sédillot, since then performed unsuccessfully sixteen times, has this time been crowned with complete success, under the hands of M. Verneuil. Gastrostomy, literally stomacal mouth, is an operation analogous to that for artificial anus; it has been proposed to remedy impassable strictures of the œsophagus, condemning the unhappy sufferers to a certain death; generally, carcinoma or epithelioma of the œsophagus are in question, which have already induced profound cachexia. M. Verneuil's patient presented other conditions. He was a young man of seventeen, in habitually good health, who by accident swallowed a solution of caustic potash, on February 4, 1876. He immediately felt an intense burning in the throat, and soon vomited *débris* and fragments of mucous membrane. These symptoms of acute œsophagitis were quieted at the end of a fortnight, but when he tried to eat he experienced the greatest difficulty in so doing. He continued to work up to the end of March, when he went into the Pitié Hospital under the care of M. Dumontpallier. Catheterism was unsuccessfully attempted several times, and M. Dumontpallier transferred the patient to M. Verneuil's wards, where he entered on May 24. The patient was extremely emaciated, pale, and very much enfeebled; his temperature was below normal; he could not swallow. Catheterism of the œsophagus showed a very much constricted stricture at about seven centimètres below the upper orifice of the œsophagus, at a point where external œsophagotomy was impossible. M. Verneuil decided on performing gastrostomy. M. Léon Labbé, who was called into consultation, gave his advice in the conduct of the operation. No precaution was neglected. All the instruments were dipped in a solution containing a twentieth part of carbolic acid; the sponges were steeped over night in the same solution, with which the surgeon and his assistants washed their hands; the suture-needles were anointed with carbolic acid; finally, throughout the operation a jet of carbolic water-spray was directed on the wound. The patient was chloroformed, and an incision was made, five centimètres long, parallel to the edges of the left false ribs, and consequently oblique

downwards and outwards. The incision was made into the skin, the subcutaneous cellular tissue, and the great oblique muscle; the peritoneum was then reached, which was raised with a pair of claw-forceps and divided with scissors. The stomach, easily recognised by its white colour, was seized with claw-forceps; it was drawn into the wound, and two long acupuncture needles passed through it perpendicularly to the lips of the incision, so as to keep the stomach-wall in contact with them. The edges of the peritoneal opening were then taken hold of with hæmostatic forceps, held by the assistants; a metallic suture fixed the peritoneum to the wall of the stomach with fourteen loops, tightened with a leaden tube over a shirt button; the two large acupuncture needles were afterwards removed. This done, the wall of the stomach was cut into, the thickness being considerable, and in no way resembling what is seen in the dead body; across the opening thus made was introduced a large tube of vulcanised India-rubber, and was fixed with a silver thread, which also passed through the stomach-wall. From seven to eight centimètres of the tube passed into the stomach. The incision of the stomach brought on a copious hæmorrhage, which was stopped by hæmostatic forceps; the abdomen was then covered with collodion, and the operation was finished. No accident supervened, the sutures fell off quickly, and after the first few days the patient was able to take liquid food by the stomach. At the time the operation was performed, the patient weighed thirty-three kilogrammes; the next month he weighed thirty-four, and at the time M. Verneuil read his paper, forty-two. He takes food and benefits by it; his appetite is good. When food is poured into the stomach, his mouth performs masticatory movements. The success of the operation, therefore, is complete. M. Verneuil insisted on the considerable difference existing between his patient and M. Beaumont's famous Canadian, who could swallow, and took his food by the mouth, whilst the patient in question is suffering from an impassable stricture of the œsophagus, which will probably end in complete obliteration. He appears destined to suffer from this affection all his life, and to feed himself by the injection of nourishing foods into the stomach.

October 31. *Cauterisation of the Pharyngeal Mucous Membrane in the Treatment of Amnesia.*—M. Bitot pointed out the good effects obtained in certain cephalic neuroses, notably in amnesia, by the cauterisation of the back of the throat. He comes to the conclusion that it is by the medium of the superior cervical ganglion that this modification of the pharyngeal and mucous membrane produces these favourable effects.

Feeding of New-Born Infants.—M. Hervieux, reverting to the question of the alimentation of newborn children, contested the opinions expressed by M. Magne, and protested against the theories which ranked human nurslings with young animals. Milk only will suffice for alimentation up to the fifteenth month; if it be impossible for the mother to suckle, resort must be had to pure cows' milk. Mixing water and alimentary substances with milk is the origin of a great many of the affections of early infancy.

November 7. *Feeding of New-born Infants.*—M. Devergie laid before the meeting some reflections on the quality of the milk and the selection of the nurse. The microscope affords valuable indications on the amount of fat-globules and the choice of the nurse. Large breasts do not give the purest

milk. It is the form that exercises an influence on the qualities of the nurse; pyriform breasts are generally an indication of a good nurse.

Stricture of the Urethra.—M. Lefort gave a description of his method of treatment in strictures of the urethra by immediate and gradual dilatation. He inserts in the stricture a fine bougie, having at the extremity a piece of metal without a screw. He screws to it a small plate which keeps it in its place for at least twenty-four hours. The mucous membrane, owing to the presence of the bougie, secretes and becomes supple to such an extent that the bougie which was at first confined in it works freely. This accomplished, he unscrews the plate and replaces it by a conical bougie, of which the diameter at the point is similar to the flexible bougie and of which the largest diameter corresponds with Charrière's No. 10. He inserts the metallic bougie into the canal, and it pushes before it the flexible bougie which draws itself back into the bladder; he gently inserts the sound which cannot go astray owing to the conducting bougie, and the dilatation is begun. He then replaces No. 1 sound by No. 2, of which the diameter is the same at the point, but which increases until it equals No. 15 of the gauge; he then introduces No. 3, which, in the largest part, equals No. 20 of the gauge. When this is done, the stricture is at an end, the patient is instructed how to apply the sound for himself, and the surgeon's business is finished.

Feeding of New-born Children.—M. Blot, in relation to the feeding of new-born infants, said that he believed that it is a pure prejudice to think that the age of the nurse's milk should correspond with the age of the child. More mature is often preferable to very young milk.—M. Devergie protested against this view, which he asserted to be contrary to the laws of nature; he believed that there is a distinct advantage in taking a nurse whose milk is as nearly as possible the same age as the infant.

Properties of Maize.—M. Fua, of Padua, read a memoir on the hygienic and therapeutic qualities of maize. He believed that the use of this food calms the passions, and should be employed in the violent delirium of insanity. Pellagra has been wrongfully attributed to the use of maize, but it is due solely to poverty and debilitating influences. Maize is really a very healthy food, valuable for its nourishing as well as for its therapeutic properties.

ACADEMY OF SCIENCES OF PARIS.

Igneous Utero-Vaginal Myotomy.—M. Abeille submitted clinical observations on the cure of hypertrophic elongation of the neck of the uterus by igneous utero-vaginal myotomy. The writer had already made known the successes which he had obtained by this method in flexions of the uterus. He now demonstrated that he could radically cure the hypertrophic elongation of the whole of the neck and part of the body of the uterus; whether it be accompanied or not by prolapsus of the organ, and narrowness of the meatus, whatever may be its complications.

October 30. *Cholera.*—M. Ch. Pigeon presented a memoir entitled *Refutation of the Doctrine of the International Congress of Constantinople on the Cholera.*

The Embryo in the Hen's Egg.—M. Daresté communicated his researches on the nutrition of the embryo in the hen's egg. The albumen necessary for

the nutrition of the embryo does not contribute to the nutrition of the blastoderm itself. This seems rather to develop itself at the expense of the yolk.

Influence of Poisoning by Agaricus Bulbosus on the Formation of Sugar.—M. Oré contributed a note on this subject. 1. In dogs which have succumbed to the action of agaricus bulbosus saccharine matter is neither found in the blood, nor in the liver, eighteen, eight, six, or five hours after death. 2. On the contrary, saccharine matter is found, and that constantly, in all the animals on whom these mushrooms have been employed; if the blood in the liver be examined immediately before death or immediately after. 3. The absence of sugar in the first-mentioned is not therefore connected with a destructive influence exercised by the agaricus bulbosus on the glycogenic function; it confirms the theory that M. Claude Bernard formulated some time since in these terms: 'Sugar does not regenerate itself in the blood after death, but it continues to destroy itself there; that is why no more is found, neither in the blood-vessels nor in the heart at the end of a certain time; but if this negative experiment made after death leads to the conclusion that sugar is not present in the blood, during life an absolutely false conclusion will be arrived at.'

The Employment of Picric Acid in the Treatment of Wounds.—M. Eugène Curie recommended picric acid in a watery solution with which the dressings are saturated, or, better still, picrated wadding, that is to say, pieces of dry wadding in which picric acid has been incorporated; the last method is generally the most convenient in application. This method, according to the author, affords the advantage of completely suppressing suppuration.

November 6. *Use of Iodides in Lead-poisoning.*—M. Faure forwarded a note on the efficaciousness of the iodides in lead-poisoning. These observations had been made by the writer in a white-lead factory, his own property. He made the experiment on himself after a very prolonged period of poisoning, and a partial cure only by the usual remedies; he obtained excellent results by a treatment of iodide of potassium, administered in doses of two centigrammes. After that time, and notwithstanding an excessive sensitiveness to saturnine emanations, he had always successfully overcome frequently repeated poisonings. M. Faure was of opinion that a workman sufficiently intelligent to determine the quantities he ought to take, would always obtain the most satisfactory results, by a treatment consisting of doses of from 5 to 10 centigrammes of iodide of iron or potassium, without being obliged to interrupt his work.

REVIEWS.

A Treatise on the Theory and Practice of Medicine.

By JOHN SYER BRISTOWE, M.D. London, F.R.C.P., Physician to St. Thomas's Hospital, Joint-lecturer on Medicine at the School, and Examiner in Medicine to the Royal College of Surgeons; formerly Examiner in Medicine to the University of London, etc., etc. London: Smith, Elder, and Co. 1876. Pp. 1166.

Our medical students have now no lack of text books in medicine. We only lately reviewed Dr. Roberts's Manual, whilst those of Watson, Aitken, Tanner, Austin Flint, and others, have each their

admirers, and their own special excellences. As a rule, the one-volume treatises are the favourites for reading for examination. In the present volume (which is a thick, large octavo, well got up, and with singularly few misprints), we have a work by one who has long been, and still is, not only a lecturer, but an examiner in the very subjects of which he treats. It may therefore be assumed with some show of probability, that the author has kept in mind the special needs of medical students. Nor is the expectation disappointed when we open the book. But it must not be assumed that this volume is for students only who are reading for examinations. It well deserves a place in the library of every physician and of every practitioner of the medical art. It does not deal with obstetrics proper or the surgical diseases of women, but apart from these, those diseases of the fair sex which have a general interest for all practical men, such as metritis, oöphoritis, ovarian cysts, etc., are mentioned (somewhat briefly it is true) in their place. After a very excellent summary of the general principles of medicine and pathology, the febrile exanthemata are discussed in about 150 pages. Skin-diseases take 50 more, then come diseases of the respiratory and circulatory organs, which bring us up to the 564th page. Diseases of the ductless organs and blood, of the digestive tract, including the liver and pancreas, and of the genito-urinary organs occupy about 300 pages more. Gout, rheumatism and their allies, rickets, mollities ossium, and pseudo-hypertrophic paralysis, are all grouped together as diseases of the organs of locomotion; we presume for the sake of convenience, rather than for any more scientific reason. Then the last 200 pages or so of the book are filled with an account of the diseases of the nervous system. This was rather the weakest point of Dr. Roberts's book. It seems to us the strong point of Dr. Bristowe's. How well he enters into all these subjects, will be seen from the account of radial or musculo-spiral paralysis which we extract.

As might be expected from Dr. Bristowe's antecedents, pathology and prophylaxis are most carefully rendered, and form a distinguishing feature of the work. As in all the modern works on physic, the treatment of disease receives less attention in this treatise than its diagnosis and *post mortem* phenomena. We think this is to be deeply regretted on more grounds than one. The neglect of treatment on the part of orthodox practitioners is the stronghold of quackery. The self-dubbed Doctor Smell-fungus, graduate of a college *in nubibus*, sees a patient, relieves his pain, gives him tranquil nights, and at least a few days of enjoyable life, whilst the graduate in honours of old and celebrated universities, who is perhaps, in addition, Member or Fellow of Royal Colleges of Physicians or Surgeons, sends the patient away, or leaves him, after making an elaborate diagnosis, with some peppermint water, or some other equally futile prescription, which affords no relief either to his body or to his mind.

Dr. Bristowe's book is no worse than others in this matter. It is perhaps rather better. But unless something be done to advance the study of rational therapeutics, quackery must and will flourish in our island. We must, too, reckon as a minor blemish the sort of careless style in which the writer discusses the operation of paracentesis thoracis, or thoracocentesis. To tell medical students that 'it is indeed of little consequence if, in attempting it, we wound the lung or the kidney or other

neighbouring organs' (p. 425) is, in our humble opinion, to encourage a recklessness which is, to say the least, unscientific. There is no need to wound any of the organs named. *Experto crede.* We speak of things we know, having performed and witnessed the operation named, not in one or two, but in several hundred instances.

But apart from this, the work is one that will greatly enhance its author's reputation. We prophesy that it will be the favourite for the examinations of the London and other universities and the College of Physicians; whilst many who never pass these examinations, but content themselves with Hall and College, will be glad to purchase a book which, once acquired, they will not wish to part with, but will carry with them to their residence in the country, or to the distant colony, on board ship, and even in the knapsack on the march with troops. As a specimen of the style, as well as illustrating the careful treatment which nervous diseases receive, we quote from the description of 'Paralysis of the Spinal Nerves,' (pp. 1115, 1116).

'*Causation.*—Paralysis of these nerves may arise under various conditions; but we propose to refer only to those varieties which M. Duchenne speaks of as paralysis from cold, and in which the paralysis is due to inflammation of the trunk of the affected nerve. These affections are not uncommon, and may be readily mistaken for ordinary rheumatism.

'*Symptoms and Diagnosis.*—The symptoms comprise pain and tenderness in the course of the affected nerves, and febrile disturbance, together with the various consequences of disease involving mixed nerves, namely on the one hand, burning or shooting pains, in the course of the branches of the implicated nerve, and hyperæsthesia followed by tingling and numbness; on the other hand, muscular paralysis, followed by speedy loss of electric contractility, and wasting. The muscular paralysis for the most part comes on later than the symptoms referable to sensation. During the early period of the disease the temperature in the affected parts is augmented, later on it undergoes manifest diminution.

'M. Duchenne singles out two forms of this affection for description, one of which he terms "deltoid rheumatism," the other "paralysis of the radial nerve." Affection of the spinal accessory is also not uncommon.

'1. *Deltoid Rheumatism* is essentially inflammation of the circumflex nerve. It is marked by the occurrence of violent neuralgic pains in the deltoid muscle, sometimes coming on in paroxysms, and augmented by any movement of the shoulder. In voluntary movements pain is especially excited in those fibres which are brought into contraction, a circumstance which will help to distinguish the affection from ordinary articular rheumatism. The symptoms may last for a few days only, or be prolonged for months. In many cases convalescence takes place without the occurrence of complications, but in some cases atrophy of the deltoid, or of some part of it, supervenes after the pains have continued for awhile; and when at length, under these circumstances, the pains have subsided, the muscle continues atrophic although retaining its voluntary and electrical contractility. In other cases paralysis attended with more or less complete abolition of electrical contractility supervenes in the course of the disease.

'2. *Paralysis of the Radial or Musculo-Spiral*

Nerve, is sometimes referred to pressure on the nerve, occurring, for example, during sleep, but by M. Duchenne is attributed (like Bell's paralysis) to exposure to cold, especially to exposure of the arm during sleep to a current of cold air, or to cold and damp. It generally comes on suddenly, without pain or tenderness, but with numbness or tingling, extending to the tips of the fingers. The paralytic symptoms have a very close resemblance to those of lead poisoning, and, like these, comprise as an essential feature dropping of the hand, and inability of extending the fingers. The differences between them are, as M. Duchenne points out: first, that in paralysis from cold the paralysed muscles retain their electrical contractility unimpaired, whereas in lead palsy this quality rapidly diminishes or disappears; second, that the supinator longus, which never suffers in lead poisoning, is invariably implicated in the present case. The proof of implication of the supinator longus is obtained, according to M. Duchenne, in the following manner. "If, when the patient has placed his forearm in the position of semiflexion and semipronation, he attempts to flex it more completely (the attempt being opposed), the long supinator can neither be seen nor felt to contract. This is the indication of paralysis of this muscle, which, as I (M. Duchenne) have proved experimentally, is the flexor of the forearm while it occupies the semi-prone position."

'As in lead-palsy, the flexor muscles of the forearm and hand and the interossei escape. Paralysis of the musculo-spiral nerve from cold is almost always followed, sooner or later, by recovery. In some cases, however, progressive wasting of the affected muscles comes on; and occasionally, also, the opposing muscles and the interossei become manifestly enfeebled from want of use.

'*Treatment.*—The value of galvanism in the treatment of the above forms of paralysis is very great. When the deltoid pains are unattended with fever or local signs of inflammation, M. Duchenne strongly recommends the use of cutaneous faradisation, effected upon a dry surface, with a feeble and slowly intermittent current. When, however, there is wasting or paralysis, faradisation of the muscles or the continuous current is especially indicated, both in the case of the deltoid and in that of the muscles of the forearm. In both of these cases, moreover, frictions, stimulant applications, and blisters are often serviceable. When there is distinct evidence of inflammation, the various forms of galvanism are not only inefficacious, but injurious. The ordinary remedies for local inflammation are then called for.'

Dr. Bristowe's section on the condition of muscles in motor paralysis, and the paragraph relating to aphasia as a symptom in hemiplegia (pp. 927 and 944, etc.), may be mentioned as especially good parts of a volume which is of more than usual excellence as a manual and index of diseases.

W. BATHURST WOODMAN.

Transactions of the College of Physicians of Philadelphia. Volume IX. (Third Series, Volume II.) Philadelphia: Printed for the College, and for sale by Lindsay and Blakiston. 1876.

This handsome 8vo volume of 186 pages is well printed and almost profusely illustrated, for there is a chromolithograph and twelve woodcuts to illustrate Dr. Weir Mitchell's paper on nerve-injuries, besides two cyrtometric tracings in cases of empyema,

and twenty-three other woodcuts, illustrating the papers on excision of the knee-joint and sarcomata of the jaw and parotid gland. Although the volume issues from a College of Physicians, a large portion of it is filled with what we in England should call surgery. We state this as a matter of fact merely, and in no spirit of fault-finding, for its contents are of more than average value.

After the list of officers and fellows comes a memoir of Dr. George W. Norris, late vice-president of the college, and for at least a quarter of a century surgeon to the Pennsylvania Hospital. Descended from a resident of the Isle of Wight (who was one of the five Quakers who sent a letter to Cromwell, begging him to let them take the places of certain Friends who were imprisoned for conscience sake), and who afterwards settled in Jamaica, conscientiousness appears to have been a leading feature in Dr. Norris' character. His biographer tells us that 'he never operated or sought an operation for his own sake, or for that of the arena. He operated publicly, in the line of his duty, and always sought to make both the operation and the lesson good ones. He would give a brief account of the case beforehand, and reserve his comments until the operation was over. Rarely, until all was done, would there be a word, even of explanation. With him the Ego was at a discount, the patient was everything. Perhaps he carried this style to an extreme; if so, we have to say of it that in the old times it was an extreme on the side of humanity, and in these days of anæsthesia it is an extreme on the side of safety.'

A list of his published writings fills two pages. Many of them have been collected into one volume under the title of 'Contributions to Practical Surgery.' His paper on 'Fracture and Dislocation of the Astragalus, (*American Journal of the Medical Sciences*, vol. xx. 1837) and the essay upon 'The Occurrence of Non-Union after Fractures' are perhaps the best known in Europe of these works. It is said of him that 'Dr. Norris was a man of truth. He never flattered, and he never sneered. Well may we wish that not only we, but many more of his profession, were such as he was.'

This memoir is written by Dr. William Hunt, whilst Dr. Ingham contributes a memoir of Dr. John S. Parry, late President of the Obstetrical Society of Philadelphia, and Obstetrician to the Philadelphia Hospital. He was born in 1843, and, as he died on March 11 last, was only thirty-three years of age. Although so young, he had already distinguished himself, and is known by his 'Observations on Relapsing Fever as it occurred in Philadelphia in the Winter of 1869-70.' After this, three other papers attracted especial notice. The first was on the subject of rickets, which, the result of careful inquiries showed him, 'was scarcely less frequent in Philadelphia than it is in the large cities of Great Britain, and the Continent of Europe.' In the Philadelphia Hospital and in his dispensary practice he found that 'at least 28 per cent. of all the sick children between the ages of one month and five years who came under his observation were rachitic. Another important paper was one on 'Inherited Syphilis.' His next paper (in the spring of 1873) was on the 'Comparative Merits of Craniotomy and the Cæsarean Section in Pelves with a conjugate diameter of two and a-half inches,' in which he carefully arrived at the following conclusions.

'1. If gestation has advanced to the full term and the conjugate diameter of the superior strait be two and a-half inches, craniotomy affords the mother no better chance for recovery than the Cæsarean section; and if the diameter be two inches or less, exclusive of the soft parts, it is the duty of the accoucheur to perform gastro-hysterotomy rather than craniotomy.

'2. The recorded histories of cephalotripsy in such cases afford us no evidence that it will compete with the Cæsarean section in safety, while the French and German experience seems to show that cranioclasm is both more safe and more efficient.' This paper led Dr. Hugh L. Hodge to prepare his article on 'Compression of the Fœtal Head by the Forceps and Cephalotribe.' The preparation and printing of Dr. Parry's book on 'Extra-uterine Pregnancy,' and his valuable additions to the second edition of 'Leishman's Obstetrics' appear to have proved too much for Parry's strength, which had been undermined in 1874 by pulmonary hæmorrhage and pleuropneumonia. His biographer remarks that there are two lessons to be learned from Dr. Parry's life and death. 'The first shows how surely a man, possessing ability, honesty, and industry, even though a stranger, can become so prominent in his profession, that when he dies, not only is a profound grief felt by all his friends and acquaintances, but a deep sense of the great loss to the profession to which he belonged is realised by all his contemporaries and co-workers. The second is the absolute necessity of physical and mental rest, if the full measure of our lives is to be run out. Had Parry better comprehend this last, and acted on its teachings, he might yet have been spared to us.' His published writings also fill two pages of the Transactions with their titles.

Dr. Hutchinson's paper relates the history of a case of left-sided empyæma, in which, after the aspirator had been used repeatedly, a cure followed the introduction of one of Chassaignac's drainage-tubes. 'The operation was performed by entering a large needle, with an eye near the point, at the seventh interspace, and bringing out the point at the ninth interspace, a little posterior to the mid-axillary line. The needle was then threaded with the India-rubber tube and withdrawn in the reverse direction to that by which it had been passed into the chest, bringing out through the upper opening one end of the tube while the other end remained outside the lower opening. The two ends were loosely tied together, in order to prevent slipping, and the boy was sent to bed.' The cyrtometric tracings show that very little deformity had resulted.

Dr. Louis Starr records the case of a child, aged five, who passed twenty to thirty lumbricoid worms at the end of April, and in the middle of May had an oval tumour in the right hypochondrium, which proved to be a hepatic abscess. As there was distinct pointing, it was opened by the aspirator, which became plugged. A poultice was then applied, pus soon escaped freely, and by January 5 not only was the wound healed, but there was scarcely any traces of the cyst or sac of the abscess.

Dr. Cleeman's 'Report on the Meteorology and Epidemics of 1875;' Dr. John Ashhurst's paper 'On Excision of the Knee-joint,' with Dr. Packard's comments, and Dr. H. L. Hodge's 'Cases of Excision of the Knee in Adults,' and Dr. Weir Mitchell's article 'On Injuries of Nerves,' deserve special abstracts.

Dr. Cohe's paper 'On the Therapeutic Uses of Compressed and Rarefied Air,' Dr. Harrison Allen's

'Note on the Anatomy of the Perinæum;' Dr. Harlan's interesting paper 'On Hysterical Affections of the Eye;' a paper by Dr. Forbes 'On Gunshot Wounds of the Thoracic and Abdominal Cavities;' another by Dr. Morris 'On Calculous and Cystic Degeneration of both Kidneys;' and Dr. Ewing Mear's 'Cases of Sarcomatous Tumours' mentioned above; together with a short article and history of a case of 'Diabetes Insipidus treated by Ergot and Gallic Acid;' complete a volume which we have seldom seen equalled either in interest or importance by any similar compilation of the same size.

W. BATHURST WOODMAN.

On the Object and Aim of Psychiatry. An introductory Lecture by Dr. EDUARD HITZIG, Professor of Psychiatry in Zürich. 1876.

Dr. Hitzig contrasts the number of insane persons confined in asylums in the canton of Zürich with the number in England and Prussia. In Zürich the number of insane is as 1 to 252 of the population; in England and Prussia as 1 to 400 and 1 to 450 respectively. The author regards as the highest object of psychiatry the prevention of the origin of psychical diseases. As the most common cause of disease, the author points out heredity. Insanity must be regarded as a disease of the nervous system, which does not always produce the same form of disease, and may arise from other forms, so that epilepsy, deaf-mutism, and such diseases, may alternate in different generations. It is not to be believed that all the children of a person who at one time has suffered from insanity *must* be insane. Many may remain free, and may perhaps be characterised by uncommon endowments. The author points out the great importance of not overworking the brain in children whose parents have shown a tendency to insanity.

The effects of dipsomania upon the person himself and his posterity are then discussed. The children of drunkards inherit the same if not a greater tendency to disease of the nervous system than the children of nervous, or even of insane, parents; in fact, they die often at a younger age from convulsions and other epileptiform conditions. With the cure of acute *delirium tremens*, little good is obtained. If the patient is to obtain the necessary power to resist temptation, he must remain for several months after the end of the acute stage under strict supervision. The question of limiting the personal freedom in such cases is discussed and answered in the affirmative.

The causes of the persistence of insanity are then discussed. The appropriate use of asylums is regarded as of great importance. The chances of a cure become rapidly smaller with every week that the patient comes later into the asylum. According to Nasse, with a duration of the disease for one month before admission, 57.5 per cent. were cured; from seven to twelve months 9.1 per cent.; and for more than twelve months only 2 per cent. The author is strongly of opinion that an examination in psychiatry should be made compulsory upon the student.

WM. STIRLING, D.Sc., M.D.

A Directory for the Dissection of the Human Body. By JOHN CLELAND, M.D., F.R.S. London: Smith, Elder and Co. 1876.

The Professor of Anatomy and Physiology at Galway, well known for his original researches as

as well as for the share he took in the past editions of Quain's 'Anatomy,' has produced a small work which promises to be of much service to first year students. The book is similar in plan to the works of Bischoff and Mayer, but more modest in scope and also differs from them in being devoid of illustrations. But this omission is intentional. Dr. Cleland says in his preface, 'The following pages have not been written with the view of interfering with any works of anatomical demonstration or systematic anatomy already in existence, but are intended to supplement such books.' An apology for this little work was hardly needed; and even if Dr. Cleland had chosen to undertake the great labour of writing a much larger work, we fail to see how any one could call it an interference. We take it that when a writer brings out a new work he does so because he thinks he has something fresh to say, or has a different and what he deems a clearer way of putting the subject before the student or practitioner, and not merely with the view of interfering—commercially—with any previous work. The first chapter gives a concise description of the instruments needed and the method of using them, and the second occupies a brief space on the *order of dissection*. With Dr. Cleland's arrangement we quite agree, as long experience in dissecting-rooms has taught us that, immediately after the dissection of the perinæum, the body should be turned on its face and the dissection of the back and spinal cord at once proceeded with. These parts are much neglected by students, and unless they be made to do them at once, by the time—as in the ordinary way—they come to dissect the spinal cord they have the valid excuse that it is too decomposed. This method has the further advantage that it does not interfere with the dissectors of the head, neck, and limbs, who can be doing the posterior portion of their respective parts.

This book is intended to be read before the student begins the study of his part with the ordinary dissectors, and only pretends to deal *generally* with the dissection of the various regions, etc., and to give a rapid survey of the methods to be adopted and the points to be observed. No attempt is made to be very precise, as it is not the intention of the author to supplant other works. The remaining chapters deal with the lower limb, head and neck, thorax and abdomen and pelvis, and, as far as they go, contain excellent instructions.

The method of dissecting the internal ear is omitted, perhaps because the author addresses himself only to the beginner, for whom this would be too difficult a task.

We can conscientiously recommend the book to first-year men, and advise them to become thorough masters of its clear directions before attempting to work at their parts with larger books.

Lesions of Vessels in Fractures of the Leg. By DR. NEPVEU. Pp. 48. Paris: G. Masson. 1876.

A few observations made in M. Verneuil's wards led Dr. Nepveu to extend his researches into the literature on these lesions. He divides his subject into two parts; the first is general, on the lesions of vessels in fractures of the leg; the second is on the accidents which follow them. The general part includes an analysis of a collection of 53 cases, which he has arranged under the following heads: (1) vessels most frequently injured; (2) anatomical

conditions which favour the action of violence on the arteries; (3) the determining causes, such as direct fractures in 28, and indirect fractures in 7; (4) the intensity of the violence; (5) resistance on the part of vessels; (6) the mechanism of the lesion, which may be direct or indirect; (7) the nature of the lesion, a complete rupture, incomplete or lateral, longitudinal fissure, rupture of the two internal coats, punctured wound, single or multiple; (8) the signs and symptoms of rupture of an artery; (9) the diagnosis of an arterial wound; (10) the prognosis.

In the 53 cases, the anterior tibial was wounded in 23, the posterior tibial in 9, the peroneal in 3, and the nutrient artery in 2.

Veins are commonly injured, but Dr. Nepveu observes that authors fail to record any particulars about them.

The wounds in 22 cases were reported to have been in the lower third of the leg in 11, upper third in eight, and middle third in three cases. Most frequently the wound had been inflicted by direct action, as by section, laceration, or puncture. Sometimes it occurred by force acting at a distance, or by indirect action.

The following signs of a wound of an artery are mentioned—absence of pulsation, peripheral, or in the continuity of the vessel, diminution of temperature, loss of sensation, hæmorrhages, infiltrations, collections of blood, aneurisms, and gangrene.

In the second part he divides wounds of arteries in fractures of the leg into two chief classes: primary or immediate, and secondary or consecutive. In twenty instances of the first class he mentions 11 as presenting external hæmorrhages, 2 collections of blood, 1 infiltration, and 3 diffused aneurisms.

In thirty instances of the second class, 11 presented false aneurisms, 15 secondary hæmorrhage, and 3 gangrene.

Incisions into collections of blood are to be avoided for two reasons, the risk of hæmorrhage from the wounded vessel, and suppuration at the seat of fracture. Only when considerable bleeding ensues upon suppuration, is interference called for; then ligature should be applied locally or at a distance.

Slight infiltration should be treated by compression, by means of a many-tailed bandage, and the ligature, local or distal, is only to be resorted to when every other means has failed. The local ligature entails the conversion of the simple into a compound fracture, and the distal ligature is too dangerous. In 204 cases of ligature collected by Cocteau, 39 cases of gangrene occurred. He quotes a case of M. Verneuil's in favour of the treatment by compression.

In reviewing primary hæmorrhage he found the treatment varied greatly, but might be reduced to four kinds: (1) ligature of both ends of the vessel, which he represents as the preferable method; (2) plugging, with or without compression of the femoral trunk; (3) ligature of the femoral (not always practicable from atheroma or multiple lesions); (4) immediate amputation. This operation may be demanded by complications, but rarely by primary hæmorrhage only.

Secondary Hæmorrhage.—M. Nepveu has found fifteen cases of this accident. Of these, the earliest took place on the fifth day, and the latest on the seventy-fifth. These cases do not throw much light on the causes of the bleeding, for the anatomical examination has been too frequently incomplete. He con-

siders the treatment under two heads—first, the prophylactic; and, secondly, ligature of the femoral or amputation. If, in spite of having hermetically sealed the wound when small, extracted loose fragments, resected the pointed ends of the bones, ligatured both ends of the vessel, and assiduously employed antiseptic dressings—if, in spite of these precautions, secondary hæmorrhage take place, then ligature of the femoral is indicated; and if the general condition be serious, probably amputation is demanded.

Aneurisms.—He distinguishes two varieties—first, the diffused or false primary; secondly, the circumscribed or false secondary aneurisms; the latter being very rare, and both of these are to be distinguished from interstitial pulsatile hæmorrhages.

He has collected notices of fourteen cases of aneurisms, but they are wanting in full details of the anatomical structure of the tumours, and of their subsequent transformations. He examines the subject under the following heads—the vessels wounded, the etiology, the symptomatology, the progress, diagnosis, prognosis, and treatment.

The anterior tibial artery was injured six times, the posterior tibial twice, the peroneal once. It is uncertain which artery was wounded in the other cases.

He can only say of the causes that they are very various and complex. The primary aneurisms are the direct consequence of violence, and probably depend on the permanent gaping of the wound in the vessel; whilst the secondary, which appeared between the thirtieth and fortieth days, may have ensued upon the fretting of a spicule of bone against the walls of the artery, or upon ligature, or upon peri-arterial abscess, or, as the author suggests on the dilatation of a weak arterial cicatrix, when the support of the dressings has been suddenly taken away. About the date (between the 30th and 40th days) after the appearance of the aneurismal swellings, the dressings are commonly removed for the purpose of examining the state of union of the fracture. When the patient begins to walk too soon, does he not impose upon the feeble cicatrix of the vessel too great a tension?

The study of the symptomatology does not enable Dr. Nepveu to point to any pathognomonic sign. Whether they are primary or secondary in origin, their symptoms are alike when once the aneurisms are formed.

He quotes Cruveilhier to show that these lesions may occasionally undergo spontaneous cure.

The prognosis is not so grave now as it was at the beginning of the century. Treatment by compression has improved the prospect of a cure to a remarkable extent.

The treatment he divides into two kinds—the first involving bloodshed; the second being bloodless, namely, by compression, and the expectant treatment.

Of the four procedures—amputation, opening of the sac and plugging, ligature above and below the wound in the artery, and the distal ligature—the author advocates the last named, for completeness, precision, and relative safety. This operation was inaugurated by Dupuytren in 1809, and repeated by him later. It has its dangers and inconveniences, however; these consisting of the risk of gangrene of the limb, delayed union of the fracture, and the creation of a second wound.

The bloodless kind of treatment by compression, digital or mechanical, offers an incomparable sim-

plicity, and perfect innocuity. He refers to a successful case of M. Verneuil's. The man was cured in less than five weeks.

Gangrene.—From fractures of the femur, gangrene is less rare than from fractures of the leg, and this may be explained by there being but a single arterial trunk. Jourdan (*Thèse de Paris*, 1873), reported sixteen observations of laceration of the femoral artery in fractures, and ten resulted in gangrene. The disadvantages of the single trunk may be compensated by the numerous anastomoses of its branches. Gangrene of the leg after fractures ought to be more rare, for there are three large trunks to maintain the life of the limb.

Tight bandaging, compression of artery by bones or splinters, diseased vessels, and compression by extravasated blood, are mentioned as the causes of gangrene.

On the appearance of premonitory symptoms of gangrene, the cause should be ascertained, and displaced fragments at once reduced. Pulsation may not return immediately; therefore, before amputation, it would be wise to wait. If gangrene have taken place, amputation above the seat of injury is to be performed.

The Marriage of Near Kin. By ALFRED HENRY HUTH. London: Churchill.

Whatever may be thought of its conclusions, this is undoubtedly a remarkable book. Its purport may be gathered from the following words.

'We have seen in the preceding pages that not one of the many reasons which have been advanced why marriage between near kin should be prohibited by the state can stand inquiry. We have seen that there is no natural horror of incest, and that many peoples have practised, and habitually do practise it; while, on the other hand, we have seen that whatever may be the reason of certain prohibitions which exist, they are certainly not due to any conscious or unconscious experience of any evil results. We have seen that the statistics on which so much reliance has been placed, as a proof of the harmfulness of consanguineous marriage, are, when not absolutely false, miserably misleading and defective.'

In order to prove this assertion, Mr. Huth in the first place traces the history of prohibited degrees among ancient civilisations, and likewise among a vast number of observed savage tribes. He seeks to deduce from the latter that mankind have no 'natural horror' of any sort of incest; for, as he points out, the practice of imputing relationship through the male line only, or, as in the Polynesian tribes, through the female only, renders the marriage of half-sisters and half-brothers possible even in tribes which keep a strict rule of prohibited degrees. This, though noteworthy, cannot be said to be conclusive; for, as his own collection shows, a more or less strict prohibition of kindred marriage is much more common on the whole than the contrary usage, and the existence of such a law is inexplicable except on the theory that men felt some natural impropriety in obvious intermarriage. It is, of course, curious that in this matter, as in many others, the family should have organised itself in so many different ways. In some races, the social insignificance of women seems to have induced public opinion to forget and ignore consanguinity through females altogether; while in Polynesia, in ancient Lydia, and elsewhere, the precise opposite happened.

The feeling which led to the imagination of the law of degrees, Mr. Huth does not seem able to account for. He makes a rather hesitating attempt to deduce it from the well-known practice of marriage by conquest—that savage rough and ready custom, of which even our own marriage ring is perhaps a vestige; but in our opinion he entirely fails. His argument is, that exogamy became customary in many warlike tribes which practised female infanticide, and that it became popular usage because it involved not only a wide liberty of choice, but also an exciting occasion for the display of the young brave's prowess. Hence, Mr. Huth believes, there arose a feeling that it was cowardly and mean to marry at home, and from this finally sprung up the idea of the horror of incest! Surely this is not a credible explanation. It is very probably true that the law of exogamy, common in Asia, is a form of the savage marriage by conquest; but it is much more probable that both the one and the other arose from some prior objection to take a wife from the warrior's own family or sept, than that any such 'natural horror' arose out of them—for the supposed feeling is not against *tribal marriage* in general, but against those marriages within near degrees, *family marriages* in fact, which in a large number of cases are found to be prohibited even by endogamous tribes.

The writer then proceeds to collect all the reliable accounts of small communities which for any reason are obliged to intermarry. He takes first the remarkable case of the mutineers of the *Bounty*, who, from one man, five women, and nineteen children, in 1800, had grown to seventy-nine persons, all robust and healthy, in 1830. On the other hand we have the island of St. Kilda, which is gradually becoming depopulated through infant mortality; but Mr. Huth argues that the main cause of this is trismus nascentium, which prevails to a similar extent in Iceland and Faröe, and is of course not necessarily dependent on consanguinity of marriage. Some important cases of Scotch fishing villages are given on the authority of a memoir read by Dr. Mitchell to the London Anthropological Society, from which the general conclusion seems to be that idiocy, scrofula, etc., are somewhat more common among them than usual. It appears, however, in many of these instances, that though such isolated populations of civilised races must marry in and in, they avoid to a very remarkable extent the closer degrees of consanguinity. Thus in a Scotch village only 11 couples out of 119 were first cousins; while in a Berwickshire settlement of about 420 persons, careful inquiry discovered only 7 marriages of first cousins, and none of second cousins. This is a remarkable and important circumstance, for it at once helps to account for the apparent absence of the evils supposed to follow from consanguinity, and affords a strong indication of the repugnance felt even by isolated populations to family marriage.

We are not, therefore, disposed to allow that the writer has made out his case. Indeed, he hardly seems to believe it himself, for he refuses to follow out his theory to its logical consequence by advocating the marriage of nieces and aunts, or of brothers and sisters. He seems to argue, indeed, that there is no physiological reason against this, any more than there is among animals; but he shelters himself behind the assertion that in the former cases there would often be a disproportion of age, as also between parents and children, and that brothers and sisters might be likely to marry too young. These

arguments are very far from sufficient to account for the obvious antipathy with which such unions are regarded. As we have said, it is by no means proved that there are not physiological grounds for this; but even if it were, we think that most powerful reasons against it could be derived from the nature of the family as a moral whole. Every family has a most important function to perform as the educator of its young, until it sends them out to take their place in the state. For the fulfilment of this office, our present family relations are admirably adapted; but it would be certain to lead at once to chaotic confusion, if uncles made love to heiresses, or if the simple relation of brother to sister could be complicated by possibilities of marriage.

On Catheters for Leaving in the Bladder, and Whalebone Conductors. By Dr. A. AMUSSAT. Pp. 15. Paris. 1876.

This paper is written to recommend the whalebone bougies advocated and used by the author.

To meet the exigencies of practice in treating retention of urine, such as inexperienced medical attendants in cases requiring frequent catheterism, or the accident of a false passage, Dr. Amussat had adapted to each other a slender long whalebone guide or conductor, and a catheter open at each end. The former may be used, firstly, as a guide over which a catheter can be slipped into the bladder. Secondly, when the catheter is to be changed, the whalebone guide may be passed through the silver catheter just into the bladder, the catheter withdrawn and a gum catheter introduced in its stead, the whalebone being then extracted. Thirdly, by screwing the whalebone guide into the open end of the catheter, the number of instruments may be reduced and their introduction simplified. Fourthly, this guide may be substituted for the bougie-conductor commonly used with M. Maisonneuve's urethrotome, as that bougie is apt to double up in front of the stricture, or make an elbow close to the metal fitting. Fifthly, it is useful as a guide in passing the cannula of M. Vollemier's divulsor. Sixthly, to facilitate the introduction of the lithotrite in nervous patients, and those who present prostatic hypertrophy, the female blade of the lithotrite may be tunnelled for the whalebone guide. Seventhly, in a similar way, this instrument may be made of service in guiding into the bladder Heurteloup's catheter for washing out that organ.

The rod of whalebone is made from 60 to 70 centimètres in length, and of a thickness graduated from 8 to 12 tenths of millimètres. It terminates in a smooth olive-shaped bulb.

NEW INVENTIONS.

AERATED BREAD.

After fifteen years' experience, aerated bread has firmly established itself in public favour. Nor is this to be wondered at, when we consider the very unpleasant revelations contained in the reports of Dr. Guy, and others, on the bake-houses of the metropolis. Many of the disagreeables described in these reports were, however, obviated by Dr. Daughlish's process, in which a successful effort was made to obviate the waste of nutriment by pumping carbonic acid gas into the dough, and thus to make it light as when acted upon by fermentation. The

advantages of the process are: 1. Its cleanliness; instead of the dough being mixed with the naked arms or feet, the bread, from the wetting of the flour to the completion of the baking, is not, and scarcely can be, touched by anyone. 2. Its preventing the glycogenic deterioration of the flour, which takes place in the ordinary process, and thereby obviating the necessity of using alums. Chemical analysis also shows that the flour has undergone less deterioration in bread made by the aerated than in that made by the fermentative process. Time, however, has introduced improvements in the process which materially improve the flavour and the keeping properties of the bread. These improvements consist in what is technically called the 'wine-process,' and consist in forming a wine from malt by mashing, and afterwards setting up the vinous fermentation in closed vessels. Four gallons of the so-called wine are mixed with the necessary water for a sack of flour, drawn into a closed vessel, and aerated. It is then mixed with the flour (also in strong closed vessels), and kneaded by arms driven by machinery. The dough formed is drawn off by machinery (thus dispensing with the unpleasant intervention of the human hands or feet) into the required sizes, and at the same moment as the carbonic acid gas passes out of it, the dough is raised and vesiculated and ready for the oven; the whole time required for forming a sack of flour into loaves not being more than half an hour. The effect of the new wine process on the flour is, that the gluten-cells of the starch are softened and broken up, and the dough is thus entirely altered in its character. Instead of being tough and harsh, the dough becomes soft and elastic; it is easily kneaded, requiring only half the power to work the kneading arms, and the atmospheric pressure required in the vessels is only about 20 lbs. to the inch. The use of such low pressure, besides being a great pecuniary gain, is of considerable importance in giving to the bread a soft and beautiful pile-like texture. The dough, when prepared by the new wine process, also soaks and bakes with the greatest ease. The starch of the flour is now changed into dextrine, while the gluten is uninjured, and the bread has a sweet and agreeable flavour, free from that acidity and bitterness more or less present in ordinary bread. The bread known as 'whole meal,' in which the bran is retained, is also made by the same process. To medical men, who know the value of this constituent, it will be convenient to be able to order the form of aerated bread now under notice.

PATENT NIGHT LIGHT-LAMP OR FOOD-WARMER.

All medical men know the importance of careful nursing as an adjunct to their treatment, therefore no apology is needed for introducing to the notice of the profession an ingenious yet simple contrivance, patented by the same firm on whose glycerine soap we have also pronounced an opinion. The invention in question answers perfectly both for night light in the sick room and as a food warmer. It is, therefore, of unquestionable utility in those cases where beef-tea or other restoratives are required during the night, or for the feeding of infants. Messrs. Simpsons, Payne, and Co., to ensure the perfect working of this little apparatus, supply night-lights in which accuracy of time in burning and perfect combustion are guaranteed. They can also, which is an unusual

advantage in night-lights, be extinguished and re-lighted, and also carried about in case of sudden need. Those accustomed to the care of the sick, who know how much accuracy and handiness are needed in all the appliances for their use, will value these apparently unimportant, but practically useful points.

GLYCERINE SOAP.

Messrs. Simpsons, Payne and Co., of Millwall, have brought under our notice some samples of their Glycerine Soap. As a useful application for the rough furfuraceous and inelastic skin left after eczema and other skin affections, restoring suppleness to the skin, and allaying burning, tingling and smarting, glycerine is now universally recognised by the profession. For toilet use it is also very comforting to persons who suffer from chapped hands and face during cold weather, or the prevalence of the easterly winds peculiar to our climate. The glycerine soap manufactured by Messrs. Simpsons, Payne and Co., is specially adapted for the uses indicated, inasmuch as it contains as large an amount of pure glycerine as the exigencies of manufacture allow to be added to the soap proper. The amount of alkali absolutely necessary for the cleansing function of the soap is kept as low as possible, and no cocoanut-oil enters into its composition, so that the well-known emollient properties of the glycerine are not counteracted by these substances, which have the property of rendering the skin harsh and dry. For medical purposes Messrs. Simpsons, Payne and Co. manufacture a form of their soap without the admixture of perfume, an addition which might prove of doubtful advantage in cases of extreme irritability of the skin.

MONTSERRAT LIME-JUICE.

The properties which lime-juice possesses of keeping off scurvy, and maintaining a healthy condition of the blood, are now among the most striking and remarkable facts of medicine. A long series of facts amounting to absolutely irresistible proof have shown that lime-juice, used daily as an article of diet has the power of averting scorbutic affections with great certainty. Its effect is, of course, most markedly seen in sea-voyages, where it becomes an essential prophylactic. The bad quality of a good deal of lime-juice, and the various expedients employed to conceal it, have brought lime-juice occasionally into disrepute. But the sovereign powers of pure lime-juice have now been indisputably established; and the revelations of the recent failure of the Arctic sledge-parties from want of it emphasise our former oft-repeated proofs. It is, however, essential that the pure juice of the fine fruit should be used. We call attention to the lime-juice of the Montserrat Company, because a great deal of the lime-juice in the market is made from mixed fruit—unripe as well as over ripe; and from inferior fruit. Great care, as is well known, is taken by this company to reject all but the finest fruit; the rest being used by them for the manufacture of citric acid. In the Royal Navy the distinction is now well established in favour of lime-juice of this class, but in the merchant service less care is exercised; and until our merchant sailors are protected by the use of a perfectly reliable lime-juice, such as this of the Montserrat Company, scurvy will not be banished. As a daily drink in health, this juice may equally be recommended. Mixed with

syrops, or with aerated waters, it is highly palatable as well as extremely wholesome.

MADEIRA.

The long disappearance of Madeira from the list of wines which are within the range of medical prescription, was due to the prevalence of a disease which destroyed the vines of Madeira, and for a considerable time drove the Madeira proprietors from the market. For some years the vines have revived, and the produce of the vineyards of Madeira has once more resumed its old position in the wine-list. A great deal of excellent Madeira may now be had at relatively moderate prices. We have lately seen samples of Madeira taken from the dock stock and purchased of Messrs. Henry Watson and Co., of Clement's Lane, which are in every respect worthy of the old reputation of Madeira. Clean, sound, and wholesome wines, the true produce of a fine quality of grape, they have the bouquet which tempts the palate, while they are devoid of any adulteration. The taste for Madeira is undoubtedly likely to revive, and sound wines like these are well calculated to meet the demand.

A RESPIRATOR VEIL.

It must be admitted that the ordinary respirator is but a partial safeguard against the inhalation of injurious atmospheres, and it is also greatly objected to by ladies on account of its disfigurement. Equal objection is made to silk gauze or gossamer veils, or to Shetland veils, on account of obstruction of vision. Lastly, the so-called invisible respirator is very unsatisfactory in practice. Mr. Lennox Browne, the Senior Surgeon of the Central London Throat and Ear Hospital, has for some time recommended a veil which, simple as it is, appears to answer all purposes, and to meet all objections. It consists of an ordinary piece of blonde (that without spots is best for ophthalmic reasons) about twelve inches deep, over the lower four of which is sewn a double thickness of silk gossamer. By wearing this as a veil, mouth, nostrils, and ears are sufficiently and equally protected from cold, the external atmosphere being warmed in the chambers formed by the layers of gossamer. To prevent the veil from becoming unpleasantly damp by the moisture of the breath, that portion which comes over the nose and mouth may be stiffened with a layer of very thin wire-gauze, so as to stand away from the face; and it may be prevented from blowing up by a piece of elastic braid threaded through the lower hem. These veils are also useful as a protection against dust. They are quite easily manufactured at home. Messrs. Marshall and Snelgrove have long kept them in stock, and supply them at a very moderate price.

IMPROVED BEDSTEAD FOR THE SICK ROOM AND HOSPITAL.

We have seen an extremely ingenious and effective invention of Mr. Tinsley, which enables an invalid to be moved into the sitting or reclining posture without any effort or exertion, and without disturbing the bed-clothes. There is an inner frame to the bedstead which is hinged, and which is drawn upon by a ratchet wheel and handle at the bed-head. It is by far the simplest and most effective device we have seen, and that which most completely

answers the purpose of changing the position of the patient without disturbing him, and by the act of one person. It is, moreover, so simple that it may be fitted at very small cost, and bedsteads may be made on this principle at scarcely any additional cost. It is worth the attention of all hospital managers.

DIETZ'S NEW MULTITUBULAR STOVE.

Messrs. Dietz and Co. the well-known lamp and stove manufacturers, of Carter Lane have just patented a very ingenious and useful petroleum stove. It is composed of a series of block tin tubes which are filled with water. The water being heated by one of Messrs. Dietz's Paragon burners, a considerable amount of moist heat is radiated into the apartment to be warmed. We have formed a very favourable opinion of Messrs. Dietz's new stove from practical experiment, and can pronounce it to be a cleanly, safe, economical and excellent apparatus for warming rooms without a flue, green-houses, or in fact, for any purpose of the kind where a stove is required.

RECENT FRENCH BOOKS.

Published by G. Masson.

Traité pratique des maladies des ovaires et de leur traitement, précédé d'une étude anatomique et physiologique de ces organes, de l'ovariotomie, par le docteur A.-A. Boinet. Deuxième édition entièrement revue et augmentée. 1 vol. in-8 de 696 pages. Prix : 9 fr.

Quelques remarques sur les calculs vésicaux et la manière de les opérer à la clinique chirurgicale de Kazan, par le docteur Beketow, professeur à l'Université de Kazan. In-8, avec figures dans le texte et une planche en couleur. Prix : 5 fr.

Traité du diabète, diabète sucré, diabète insipide, par le docteur Lecoorché, professeur agrégé à la Faculté de médecine. 1 vol. in-8 de 703 pages. Prix : 10 fr.

Traité de la diphthérie, par A. Sanné, docteur en médecine. 1 vol. in-8 de 634 pages, avec 4 planches. Prix : 10 fr.

Published by Germer-Baillière and Co.

Manuel de pathologie et de clinique chirurgicale, par MM. A. Jarmin, chirurgien des hôpitaux, et F. Terrier, professeur agrégé de la Faculté de Paris, chirurgien des hôpitaux. Troisième édition. Tome I, 1 fort vol. gr. in-18. Prix : 8 fr.

Manuel d'histologie pathologique, par MM. V. Cornil, professeur agrégé à la Faculté de médecine de Paris, médecin des hôpitaux, et L. Ranvier, professeur au Collège de France. Troisième et dernière partie, 1 fort vol. grand in-18, avec 133 figures intercalées dans le texte. Prix : 7 fr. L'ouvrage complet, en 2 volumes. Prix : 16 fr.

Published by J.-B. Baillière & Sons.

Études historiques, physiologiques et cliniques sur la transfusion du sang, par le docteur Oré, professeur à l'École de médecine de Bordeaux, lauréat de l'Institut. Paris, 1876. Deuxième édition, in-8 de 704 pages, avec planches et figures. Prix : 13 fr.

Contributions à l'étude des présentations de la face, par Adolphe Carpentier, docteur en médecine. Paris, 1876. In-8 de 74 pages, avec tableaux statistiques de 330 présentations de la face, observées à la Maternité de Paris. Prix : 2 fr.

MISCELLANY.

THE celebrated naturalist, Von Baer, whose name is closely connected with the study of embryology, died on November 28, at Dorpat, at the age of eighty-five.

THE College of Physicians and Surgeons of New York has discontinued all faculty prizes. Instead, they offer three prizes for general proficiency in examination.

THE Goldsmiths' Company have presented 1,000*l.* to the Chemical Society as a contribution to the fund being raised by that society for the promotion of chemical research.

A SCIENTIFIC NONAGERIAN.—M. Chevreul was recently entertained at dinner at the Café Corazza, in the Palais Royal, by eighty *savants*, in celebration of the fiftieth anniversary of his professorship and membership of the Academy of Sciences. M. Chevreul, now the oldest member of the Academy of Sciences, is ninety years old, and enjoys perfect health and mental vigour.

ROYAL MEDICAL SOCIETY OF EDINBURGH.—The following have been elected office-bearers for the ensuing year. *Presidents* : J. Graham Brown, M.B., C.M. ; Joshua J. Cox, M.B., L.R.C.P. and S. Ed. ; R. Kirk, M.B., C.M., L.R.C.P. and S. Ed. ; James Baker, M.B., C.M., L.R.C.S. Ed. *Honorary Secretaries* : J. Milne Chapman ; Robert Roxburgh, M.B., L.R.C.S. Ed. *Library Curator* : Lionel Druitt, M.R.C.S. Eng. *Museum Curator* : Chas. W. Cathcart, M.A.

At the last meeting of the Dresden Society for Incineration, 'Urne,' it was announced that at the Brussels Exhibition of Hygienic and Life-Saving Apparatus, the gold medal was awarded to the Siemens system. It was also announced that for the erection of an incinerating furnace in Saxe-Gotha, preparations for which have already been made, considerable contributions have been received. The agitation on behalf of incineration, it was stated, is making slow but steady progress in other countries.

THE VOICES OF ANIMALS.—Professor Landois of Freiburg has lately published an interesting work on the 'Voices of Animals,' which affords additional evidence of the universality of vocal sounds among the lower forms of animals, including the Mollusca. The author considers it as beyond all question that ants possess a vocal speech, inappreciable by human ears, by which they are enabled to exercise those higher mental faculties to which they owe the development of the advanced social organisation which they exhibit in their communities. Professor Landois' work is illustrated by numerous microscopical and other drawings of his own, and forms an interesting addition to our natural history literature.

THE PHYSIOLOGICAL EFFECTS OF CONDENSED AIR.—M. Bert, has for a long time been conducting a series of experiments with a view of determining what are the physiological effects of condensed air on the human system. Many engineering works of the day involve the necessity of workmen carrying on their operations under various pressures of air, to say nothing of the fact that the rise and fall of the barometer involve us all in changes differing only in degree from that which the diver experiences when he descends from the surface of the water to a depth of fifteen or twenty fathoms beneath it. M. Bert thinks that the influences of ordinary changes of air as indicated by the barometer are due exclusively to the varying quantities of oxygen contained in the air inhaled. The pressure of oxygen and the consequent amount of it which finds its way into the blood, he shows, depends upon the centesimal proportion of it in the air, and upon the barometrical pressure, and he says that the mischief which operatives in air-tight dresses so often experience from the density of the air they are compelled to breathe, might be completely obviated if an atmosphere were composed of air and nitrogen nicely adjusted in proportion to the pressure under which the mixture was passed along the tubes. Although it has been stated on good authority that a man may follow avocations involving the breathing of condensed air in certain cases, not only without injury, but even with advantage, there are also many cases in which injury is believed to result, and M. Bert's experiments may prove to be of great benefit to them.

QUEEN'S COLLEGES IN IRELAND.—At the conferring of degrees on Queen's University students in Dublin Castle, the Duke of Leinster, as Chancellor, acknowledged that the Government had sought to increase the efficiency of the colleges by increasing the grant to 1,600*l.* per annum for scientific appliances, and by allowing class fees to be taken into account in estimating the superannuation allowance of the professors.

THE PHYLOXERA.—The French Consul at Canton has drawn attention to a tree, the oil of which, he thinks, might be used as a preventive against the ravages of the phylloxera. The tree is the *Élaecocca Vernicia*, and the oil it yields is universally used in China for protecting the wood of houses, ships, furniture, etc., from the pernicious effects of moisture, and the ravages of insects. It renders any texture impenetrable, is a powerful sicative, and enters largely into the composition of the celebrated Japanese varnish.

THE CAP AND GOWN.—Forty lady medical students in all are, it is stated, pursuing their studies in the schools of the Faculty, and in the hospitals of Paris, of whom fourteen are English. Of the rest the majority are Russian, and the remaining number are American, German, and French ladies. Several ladies have already graduated M.D. of the University of Paris, including Mrs. Garrett Anderson, Mrs. Putnam Jacobi, Madame Brès, and Madame Ribaud; the last three all graduated with great distinction, their theses being honourably noted by the Faculty. Three lady graduates of the University of Zurich are now practising in England; Mrs. Hoggan, M.D. and Mrs. Atkins, M.D., in London, and Mrs. Walker-Dunbar, M.D., in Bristol.

DISEASES GERMINATED IN HOSPITALS.—Some interesting facts tending to confirm previous observations by others have recently been communicated to the Société de Biologie, by M. Nepveu, of the Laboratory of La Pitié. A square metre of the wall of a surgery-ward having been washed after two years, the liquid pressed from the sponge was examined immediately. It was somewhat dark throughout and contained micrococcus in very great quantity (fifty to sixty in the field of the microscope), some micro-bacteria, a small number of epithelial cells, a few globules of pus, some red blood-corpuscles, and lastly a few irregular dark masses and ovoid bodies of unknown nature. The experiment was made with all necessary precautions; the sponge employed was new, and carefully washed in water that was newly distilled.

PORTUGUESE OYSTERS.—Attention was lately called in the French Academy to the properties of the oysters called Portuguese, brought from the mouth of the Tagus. They are very much richer in bromine and iodine than those met with on the English coasts, and are a valuable article of food, well deserving the attention of hygienists, and specially suitable for preventing scrofula, ganglionic swellings, rickets, and perhaps also consumption. One kilogramme of Portuguese oysters extracted from the shell gives 700 grammes of water—a slightly violet colouring matter from the liver, 0.039 of iodine and 0.052 of bromine. The oysters cannot be cultivated further north than the warm waters of Portugal or the south of France. Near Lisbon they occupy a large bank of about 50 kilometres. They are distinguished in appearance partly by their claw-shaped shell.

ST. JOHN'S COLLEGE, Cambridge, offers for competition an exhibition of 50*l.* per annum, for proficiency in Natural Science. The examination will commence on Saturday, April 7, and will be in Chemistry, including practical work in the laboratory; Physics, viz., Electricity, Heat, and Light; and in Physiology. Candidates will also have the option of being examined in Geology, Comparative Anatomy, and Botany, provided they give notice of the subjects in which they desire to be examined four weeks prior to the examination. No candidate will be examined

in more than three of these six subjects, whereof one at least must be chosen from the former group. It is the wish of the master and seniors that excellence in some one department should be specially regarded by the candidates. Names should be sent to one of the tutors at least fourteen days before the examination,

The course of lectures at the École Libre of Anthropology, established by the Faculty of Medicine of Paris in one of their buildings, was commenced on November 15. The scheme we announced last year is an accomplished fact. The lectures will be open to the public free of charge. M. Paul Broca will deliver lectures on anatomic anthropology; M. Paul Topinard, in biological anthropology, will lecture on the history of anthropology, the general, physical, and physiological characteristics of man, and on anthropometry; M. Eugène Dally, in ethnology, will lecture on the origin and filiation of human races. M. Gabriel de Mortillet, Sub-Director of St. Germain Museum, on pre-historic anthropology; and M. Hovelacque on linguistic anthropology. The lectures will be supplemented by demonstrations in the museums and excursions to pre-historic stations round Paris.

UNIVERSITY OF CAMBRIDGE.—The following are the College Lectures in the Natural Sciences given at Cambridge during Michaelmas term, 1876:—Gonville and Caius College—On the Physiology of Digestion and Absorption, by Dr. Bradbury; On Volumetric Analysis, by Mr. Apjohn. Christ's College—On Vegetable Physiology and Histology, by Mr. Vines. St. John's College—On the Principles of Qualitative Analysis, by Mr. Main; Instruction in Practical Chemistry will also be given. Trinity College—On Electricity, by Mr. Trotter; an Elementary Course of Practical Morphology, by Mr. Balfour; Practical Physiology and Histology, by the Trinity Prælector in Physiology (Dr. Michael Foster), at the New Museums. Sidney Sussex College—Elementary Course of Vegetable Morphology, by Mr. Hicks. Downing College—On Chemistry, by Mr. Lewis; On Comparative Anatomy and Physiology, by Mr. Saunders.

THE SCIENTIFIC INSTRUMENTS AT SOUTH KENSINGTON.—The provisional managers of the guarantee fund for purchasing scientific apparatus now exhibiting at South Kensington have received from the Duke of Devonshire an intimation of his willingness to subscribe 5,000*l.* to the fund on condition that four other persons will do the same. There are in addition already five promises of 1,000*l.* each from Mr. W. Spottiswoode, Mr. Warren de la Rue, Sir John Lubbock, Bart., M.P., Messrs. Siemens Brothers, and Sir Joseph Whitworth, Bart. There are also many promises of 500*l.*, 250*l.*, 150*l.*, etc. The object of the fund is to secure by purchase those instruments now at South Kensington, 'which it may be to the advantage of science to exhibit permanently, but which, failing such purchase, would be returned to the exhibitors.' No decision on the part of the Government has yet been made known as to what will be done regarding the establishment of a permanent museum. Her Majesty's Commissioners for the Exhibition of 1851 have agreed to erect a museum at a cost not exceeding 100,000*l.*, and to place it at the disposal of Her Majesty's Government.

COMPARATIVE PHOTOGRAPHS OF BLOOD.—The *American Naturalist* for May states that Dr. J. G. Richardson, for the sake of illustrating in criminal cases the distinguishable appearances of different kinds of blood, has caused drops of blood from different animals to flow so nearly in contact on the glass slide that portions of the two drops appear in the same field, and can be photographed together. Dr. C. Leo Mees has modified this method, and obtained exquisite results in specimens presented to the microscopical section of the Tyndall Association. He spreads the blood by Dr. Christopher Johnston's method, which is to touch a drop of blood to the accurately ground edge of a slide, and then draw it gently across the face of another slide, leaving a beautifully spread film. In this way one kind of

blood is spread upon the slide and another on the cover. When dry, one-half of each is carefully scraped off with a smoothly sharpened knife, and the cover inverted up on the slide in such position as to bring the remaining portions of the film into apposition. Under the microscope and in the photograph the two kinds of blood appear in remarkably fine contrast, even those bloods that are too nearly alike for safe discrimination in criminal cases being easily distinguished when thus prepared from fresh material.

MEDICAL ASSOCIATIONS IN SWEDEN.—There are five distinct medical organisations in Sweden, which are in active and prosperous condition. The most important of these is the Medical Society of Stockholm, which meets once a week, has a large and influential membership, among which may be counted the faculty of the Carolina Medico-Chirurgical Institute. Professor E. Odmansson is the president. This association publishes not only its transactions, but also *The Hygeia*. The Medical Society of Upsala, with Professor P. Hedenius as president, consists chiefly of the members of the faculty of the university of that place. This association, which is quite an active one, publishes its transactions in bi-monthly parts. The Military Medical and Surgical Society, whose headquarters are at Stockholm, was formed last year, and has Dr. Edholm as president. It has commenced publishing a journal of military surgery, which is largely made up of the transactions of the association. The Medical Association of Gothenburg has a good and influential membership, but publishes neither journal nor transactions. The President is Dr. E. Salén, of Gothenburg. The Royal College of Health, at Stockholm, is considered to be the highest medical authority of Sweden, and has the entire medical faculty of the country under its control.

GLOBULAR THUNDERBOLTS.—In a paper addressed to the Academy of Sciences, M. G. Planté endeavours to cast some light on this phenomenon by referring to the violent thunderstorm that broke over Paris some time ago, between half-past three and four o'clock P.M., where lightning, under a globular form, struck No. 28 of the Rue des Tournelles, and a corner of the Théâtre Beaumarchais. On that occasion there was no high wind, and part of the storm cloud kept hanging for several minutes over the quarter of the Bastille; the discharges were unceasing, and several claps of thunder following upon lightning in all but continuous flashes, announced that various places of the neighbourhood had been struck. From M. Planté's inquiries it appears that the lightning fell three times on the same spot; the theatre, and the court-yard and garden of No. 28, Rue des Tournelles, the house commonly known in the quarter as the Hôtel de Ninon de l'Enclos. The stage manager of the Théâtre Beaumarchais, who happened to be in the wardrobe, a small pavilion at the top of the edifice, saw a 'bomb of fire' as big as a man's fist fall. In the Rue des Tournelles, a workman, living on the fourth storey, saw a 'globe of fire' of the size of a cannon-ball graze, in falling into the court, the edge of the roof, close to a flower-pot; the plant growing in it lost a twig on the occasion, and not more. At the same moment, another workman, on the ground floor, remarked 'three small balls of fire' on the pavement of the court, which was at that moment quite under water from the rain that was falling. Lastly, a bronze manufacturer saw 'two or three fiery lumps without any definite shape' fall into his garden, which was thoroughly swamped. M. Planté finds that his previous views have thus been confirmed. Electrified globes were formed as in those experiments in which a thread of water traversed by a powerful electric current and internally furrowed by fiery streaks reproduces the effects of a waterspout by occasioning luminous globules to be formed at the surface of a liquid into which the negative pole dips.

DEATH OF DR. T. S. WRIGHT.—We record with regret the death of a modest but devoted student of science, Dr. Thomas Strethill Wright, of Edinburgh, at the age of fifty-eight. Dr. Wright was a practising physician in

Edinburgh, but found time to make many researches, and probably a few discoveries, in various departments of science, both in biology and physics. From a memoir in the *Scotsman*, we learn that after settling in Edinburgh in 1853, he undertook a series of observations on British zoophytes, more especially those inhabiting the Firth of Forth, and not only discovered many important facts in their structure, but added to the British fauna several new and interesting forms. His memoirs on these animals, eighteen in number, were published in the *Annals of Natural History*, the *Edinburgh Philosophical Journal*, and the *Proceedings of the Royal Physical Society of Edinburgh*, and speedily attracted the attention of scientific workers in the same field both at home and abroad. He entered into a correspondence with Agassiz, Van Beneden, Claparède, Kölliker, and Allman, who in their writings repeatedly refer to the value of his observations and discoveries. But he did not confine himself to natural history studies. He was constantly at work with physical apparatus, and invented various singular forms of telephones, etc. Some of the most curious of his experiments on what are called Electric Cohesion Figures are described by himself in *Chambers's Encyclopædia*. But it is much to be feared that a great many of his most ingenious inventions and discoveries are entirely lost, as his modesty prevented him from bringing them before the Royal Society of Edinburgh, though he was frequently urged to do so. One of these was a mode of studying the scintillation of stars, by observing them through a telescope of low power supported on a vibrating stand. In 1865 Dr. Wright was made a member of the Zoologico-Botanical Society of Vienna. His ingenuity and readiness showed themselves in the mode in which he constructed out of simple materials a piece of apparatus, or devised a new method of observation, or executed the beautiful drawings with which his natural history papers are illustrated.

LADY BELL.—Lady Bell, widow of the late Sir Charles Bell, the physiologist, died last month at the advanced age of nearly ninety. Lady Bell was the second daughter of Mr. Charles Shaw, of Ayr, and was married to Sir Charles, then Mr. Bell, in 1811. When she was married to Mr. Bell, he was struggling into fame as a lecturer on anatomy and surgery in London, and she contributed not a little to lighten the burdens incidental to a successful professional career by acting as his amanuensis for some of his early popular writings, and by making the enthusiastic physiologist's home bright and happy by her buoyant disposition and agreeable manners. His *Animal Mechanics*, his *Anatomy of Expression*, and the Bridgewater Treatise on *The Hand* went to the press mainly in her handwriting. After a residence of five-and-twenty years in London, Sir Charles was appointed Professor of Surgery in the University of Edinburgh. In Edinburgh Lady Bell was famous for her elegant home and happy *réunions*. On the death of her husband in 1842 she returned to London, where she had made many friends in the scientific world during her former residence. Her married life had brought her into community with all the scientific men of the day, and this society of the learned she cultivated during the thirty-four years of her widowhood. A great reader, a woman of keen perception, with a mind capable of entering into the controversies and topics of the day, she was able to count among the friends of her widowhood many known to fame in literature, in science, and in art. These friends reciprocated her friendship not only out of respect to the memory of her husband, but out of regard for herself; for, keeping pace as she did with the age, she was always able to discourse on the last novelty with each in his own peculiar province. Lady Bell was endowed with great conversational powers. She had a ready flow of thought, and clothed her ideas in ornate and precise language. Up to the date of her last illness, though within a few months of her ninetieth birthday, she read the *Times* daily, and nearly all the new books in science and light literature, and she often put her juniors to shame by acquaintance with new matter of which they had not heard.

Her mental work was not confined to the perusal of the writings of others; she republished several of her husband's works, carried on an animated correspondence with a large circle of friends, wrote verses occasionally, and at the age of eighty-seven, edited her husband's treatise on *The Hand*.

PROFESSOR HUXLEY ON THE EVOLUTION THEORY.—A lecture was given at the opening of the session of the London Institution, on Dec. 4, by Professor Huxley, on 'Some Recent Additions to our Knowledge of the Pedigree of the Horse.' Mr. Huxley began with a comparison of the skeletons of the horse and polar bear, pointing out the similarity in the regions of the skull, the correspondence of the number of joints in the neck (irrespective of the length of the joints), the number of joints in the vertebræ and tail, and the points of agreement and those of divergence in the teeth. Dwelling chiefly on the marked differences in the bones of the legs of the two animals, and still more particularly on the distinction between the foot of the bear and that of the horse, he illustrated the gradual changes which fitted the horse for running over fields and roads, and left the bear suited for climbing and making his way over ice. Laying down the general proposition that it belonged to the general plan of mammalia to have five toes on each foot, these became reduced to four in the pig, three in the rhinoceros and tapir, two in the cow, and one in the horse, sheathed and protected similarly to the claws of the bear. The facts of a common ground plan in the horse and the bear were just as true as that an architect had a common ground plan for various structures. Paleontology furnished traces of such a transition as must have taken place in the horse if the doctrine of evolution were true. Remains of the horse in the later tertiary period were like those of the existing horse. In the remains of the upper miocene, there was a little difference in the teeth, and an extra small toe like a dew-claw. The horse of that period, ancestor of the present horse, was called 'hipparion.' Working back into the older miocene, there had been discovered in France, Germany, and the United States remains of an animal first described by Cuvier under the name of the paleotherium, a creature differing from the hipparion as much as the hipparion differed from the horse. Instead of a mere dew-claw the animal had three toes, the fibula was complete throughout, and the ulna was a distinct bone. From this Mr. Huxley passed to the great area eastward of the Rocky Mountains, where a large inland basin received in the mud of the older tertiary period the remains of animals which flocked about its shores. In these miocene rocks Professor Marsh found within the last six years remains of the antehippus, and in the oldest miocene the mezzo-hippus, in which he found the rudiment of a fourth toe. Then in the eocene was found a creature, not much larger than a fox, but having equine peculiarities, with four complete toes. So far, as thus shown, the history of the horse was exactly in accordance with the doctrine of evolution. In the lacustrine deposits, which preceded the eocene, it was certain that there would be found equine remains with five toes on each foot, and then the history of the horse would be as complete as any such history could be. The reason was such to his mind that he did not care to discuss longer the theory of evolution. What was true of the horse was true of other animals, because it would be preposterous to suppose that nature had not built others on the same plan, and carried out the same fundamental idea.

PROFESSIONAL APHORISMS.—The following collection of aphorisms was made for the *Richmond Medical and Surgical Journal*, by Dr. M. Schuppert, of New Orleans, and is published in the July number. Necroscopical investigations (autopsies) are often the grave of the finest theories, and against the logic of these facts, unfortunately, there is no appeal.—Experience only becomes useful when guided by reflection.—To individualise is the fundamental principle in medical practice.—'Qui bene distinguit bene medebitur.'—'Medicus minister, non magister naturæ.'

Anytime in which an operation is well done is quick enough.—To observe little things best characterises the great physician.—Try to learn, see with your own eyes, and avoid as much as possible to look through coloured glasses.—Never do anything in your profession without a good reason, which, whatever the result may be, will leave your conscience clear.—Keep your office, and the office will keep you.—Take great care of your first patients, ye beginners! for they are the seed from which your practice is to spring.—'La médecine est le plus noble des professions et le plus triste des métiers.'—A judicious silence is always better than the truth spoken without charity. Be cautious to tell all you actually know or have seen, even in telling the truth and nothing but the truth; nothing under any circumstances is more dangerous, and will bring you so certainly in disgrace. Truth is a dish not made for every man's stomach, and nothing ought to be handled with more care.—Medical can not be separated from moral science without reciprocal and essential mutilation.—There is no truth, however pure and however sacred, upon which falsehood cannot fasten and engrave itself.—Man is a despicable animal. There is scarcely any one who may not, like a trout, be taken by tickling. Quacks know this and act upon that knowledge.—When the blind credulity of the public in medical matters is considered, one does not wonder that there are so many quacks and impostors; but, on the contrary, that there are so many upright physicians.—The practitioner who expects his reward from the gratitude of his patients, may be likened to the countryman who waited, in order to cross the river, until the waters had done flowing.—When you want to get rid of a troublesome patient, you have but to send in your bill. We are angels when we come to cure, devils when we ask payment.—If the reward of investigation be taken away, study will be neglected.—The cheapest doctors are also the most ignorant. Cheap doctors and cheap medicines are always in close proximity to a well-filled graveyard.

THE DISEASES OF CHILE.—One of the maladies that invades this land in an almost fatal manner is the epidemic small-pox. Within these few years alone there have occurred two epidemics of the same malady, which traversed the country from north to south. The last time, above all, it became very confluent and hæmorrhagic, from which the mortality attained sometimes to 50 per cent. during a short period. It is to be observed that such ravages occur almost exclusively among the more indigent classes, originating in the absence of wholesome habits, and more especially in the non-vaccinated individuals. With us, vaccination is not compulsory. In the interval between one epidemic and the other, there are always to be seen some cases of mild variola in our cities.—Another endemic affection, becoming epidemic from time to time, is the *chabalengo*, improperly termed the typhoid fever of Chile, which corresponds exactly to the typhus fever of Ireland, as described by Graves and Stokes of Dublin. In general, this is a formidable malady in itself, and much more so when epidemic. This affection predominates in the necessitous and vicious classes in the epidemic epoch. When non-epidemic, it attacks the natives of the country periodically, but under a benign form in the generality of the cases. During the year 1873, we had an epidemic of *erysipelas faciei*, which made a great number of victims in Santiago, from taking the hæmorrhagic or gangrenous form. In 1868 and 1869 there was an epidemic of puerperal metropéritonitis, reduced to a small number of cases in civil practice. The gravity of this malady depended, in general, on the state of anæmia in which the inflammatory affection found the patients. Whooping-cough prevailed during the whole of 1873 among the children. Measles and scarlatina usually present mild epidemics during the spring season. We have had the aphthous fever, or epizootia, among the animals, imported during the year of 1871 from the neighbouring Argentine Republic by the herds imported from it to ours. Under the influence of various pathogenic causes, the following affections are endemic: The tonsillary anginas and the milder pharyngeal;

bronchitis and pneumonia; dysentery—the cholera mistero (*lapidis de calambres*); acute rheumatism; and the neuralgias. The above-mentioned recognise as the primary productive agents abrupt atmospheric changes, excesses of all kinds, which predispose by debilitating the organism, and the misery and neglect of the inferior ranks. Rheumatism and syphilis are the most frequent originating causes of organic heart disease in this country. The former is very untractable. Syphilis is sometimes so from want of appropriate treatment. In consequence of bad hygienic regimen, affections of the liver (hepatic abscess) are common. Dyspepsia and diarrhoea are also so in all ages, from similar causes; likewise the *lumbri* in children. Pustula maligna appears from time to time in country places under local pathological conditions (contact with the flesh of putrefied animals). The two forms of pulmonary phthisis (*P. caseosa* and *P. gravelosa*) are frequent and fatal, especially in the localities where the supply of the reparatory aliments is difficult. In exchange, till now, we have never had epidemic cholera among us, nor yellow fever, which on repeated occasions have decimated our neighbours in Peru and La Plata. No intermittent fevers exist in our natal soil, and the rarity is extreme that one or other case of dothienteria becomes visible.—Dr. John Boyd, in *Edinburgh Medical Journal* for August.

DR. CARPENTER ON SPIRITUALISM.—On the evening of December 7, Dr. W. B. Carpenter delivered at the London Institution a lecture on 'Mesmerism, Odyism, Table-turning, and Spiritualism, considered historically and scientifically.' He said that from the earliest period down to the latest, there was an obvious continuity in the type of the manifestations which had been produced, and he thought that this might be traced to the fact that the mental tendencies were the same in all grades of humanity, though varying in aspect, according to the general habits of thought and the amount of civilisation. Throughout there was a most remarkable similarity in the phenomenon themselves, and in the mental tendencies to which belief in them was owing. To criticise such notions it is necessary to have studied the extraordinary dispositions to self-deception and intentional deception which are admitted even by the candid advocates of spiritualist views. It is necessary to be acquainted with the modes in which exposures have been effected. The only prepossession which scientific men can allow to operate is one in favour of the observance of the laws of nature. When a table is said to rise of itself and float about beneath the ceiling, we are justified in requiring a degree of proof of such a fact which we should not require if a more ordinary occurrence were alleged. Men of science hold themselves open to the proof of any new force in nature if only it is given in the satisfactory way in which the proof of galvanism, magnetism, or electricity was made. No one can go into this kind of investigation with any likelihood of arriving at true results who is not prepared with the kind of special knowledge required for it. The instruments of which knowledge is required in this investigation are those very delicate instruments the human body and the human mind, things of peculiar susceptibility, of susceptibilities not constant. Medical knowledge in particular affords important guidance. Dr. Carpenter alluded then to the 'Ody' force of Baron von Reichenbach, to the alleged appearance of flames from a magnet, and to the pretensions of Mesmer. He also gave the history of divination by the oscillations of a ring or bell suspended, and referred to the phenomena connected with the 'divining-rod.' In a subsequent lecture he would speak of clairvoyance, which was the link, as it were, between mesmerism and spiritualism. So far from scientific men not having investigated these things, they had been investigated over and over again. There was still a lurking belief in the minds of a number of persons that there must be something in the pretensions which were thus put forward, but the only 'something' which existed was the extraordinary readiness with which men and women possessing a love of the marvellous—as if there was not sufficient

in science which was marvellous enough—embraced the abnormal manifestations of diseased minds.

UNIVERSITY OF LONDON.—The following is a list of the candidates who have passed the recent second M.B. examination:—*First Division*.—Samuel Herbert Burton, University College; Edward Joshua Edwardes, St. Mary's Hospital; John Christian Ferrier, Guy's Hospital; Thomas Colcott Fox, University College; John Gatchell Hancock, King's College, Charles Edward Harrison, St. Bartholomew's Hospital; John Benjamin Hellier, Leeds and University College; Joseph William Hunt, University College; Arthur Henry Jones, Guy's Hospital; Walter Aubrey Kidd, Guy's Hospital; William Henry Lamb, Guy's Hospital; Augustus Joseph Pepper, University College; Thomas Mark Pinnell, University College. *Second Division*.—Henry Blake, St. George's Hospital; Hugh Walter Boddy, Royal School of Medicine, Manchester; Harry Beecham Briggs, King's College; Herbert Duke, Guy's Hospital; John Geoffrey Langley, University College; Thomas Sharp Parry, University College; Rhinalt Navalw ap Joan Pughe, Liverpool Royal Infirmary; Thomas King Rogers, University College; George Frederick Rossiter, St. Thomas's Hospital; William Joseph Seward, University College.—Examination for honours. *Medicine: First Class*.—Augustus J. Pepper (Scholarship and Gold Medal), University College; J. William Hunt (Gold Medal), University College; Thomas M. Pinnell, University College; John B. Hellier, Leeds, and University College; John C. Ferrier, Guy's Hospital. *Second Class*.—Thomas K. Rogers, University College; Samuel H. Burton, University College; Arthur H. Jones, Guy's Hospital; Walter A. Kidd, Guy's Hospital; Thomas S. Parry, University College. *Obstetric Medicine: First Class*.—J. B. Hellier (Scholarship and Gold Medal), Leeds, and University College; A. J. Pepper (Gold Medal), University College; J. C. Ferrier, Guy's Hospital; Rhinalt Navalw ap Joan Pughe, Liverpool Royal Infirmary; A. H. Jones, Guy's Hospital. *Second Class*.—S. H. Burton, University College; George Frederick Rossiter, St. Thomas's Hospital; Edward Joshua Edwardes, St. Mary's Hospital; T. K. Rogers, University College; W. A. Kidd, Guy's Hospital. *Third Class*.—Herbert Duke, Guy's Hospital; John Geoffrey Langley, University College; William Henry Lamb, Guy's Hospital. *Forensic Medicine: First Class*.—A. J. Pepper (Scholarship and Gold Medal), University College; W. A. Kidd (Gold Medal), Guy's Hospital; A. H. Jones, Guy's Hospital. *Second Class*.—J. G. Langley, University College; Charles Edward Harrison, St. Bartholomew's Hospital; Thomas Sharp Parry, University College; T. K. Rogers, University College. The following have passed the M.D. examination:—George Henry Batterbury, King's College; Henry James Benham, University College; Clement Dukes, B.S., St. Thomas's Hospital; Peter Thomas Duncan, B.S., (obtained the number of marks qualifying for the medal), University College; George Garlick, University College; Vincent Dormer Harris, St. Bartholomew's Hospital; Walter Benoni Houghton, B.S., University College, and Charing Cross Hospital; Jean Arthur Hullard, B.S., B.Sc., University College; Daniel John Leech, Owens College; Walter George Lowe, St. Bartholomew's Hospital; Joseph Cooke Verco, (Gold Medal), St. Bartholomew's Hospital. *Logic and Moral Philosophy only*.—Richard Legg Batterbury, King's College; Robert Charles Brown, King's College; Richard Petch, King's College. The following have passed the recent B.S. examination:—*First Division*.—Samuel Herbert Burton, University College; Andrew Duncan, M.D., King's College; Joseph William Hunt, University College; Walter Ottley, University College; Augustus Joseph Pepper, University College. *Second Division*.—Walter Aubrey Kidd, Guy's Hospital; Thomas Sharp Parry, University College.—The M.S. Examination has been passed by Alfred Pearce Gould, University College. *Logic and Moral Philosophy Only*.—Leander Starr Jameson, University College.
